11.1 INTRODUCTION

It has been over half a century since effective treatment for psychosis was introduced into clinical practice. Chlorpromazine was the first of several antipsychotics, now called conventional or first-generation antipsychotics (FGAs), which revolutionized the treatment of psychotic disorders and enabled large numbers of individuals afflicted with these illnesses to be discharged from chronic care institutions and be cared for in the community. However, the high rate of extrapyramidal symptoms (EPSs) at therapeutic doses of these drugs was a major impediment to patient acceptability [1], and efficacy limitations such as minimal or no improvement of cognitive deficits, negative symptoms, and mood symptoms resulted in a substantial number of patients not tolerating these medications, not responding to them, or refusing to take them.

The second major step in the treatment of psychosis was the discovery of clozapine in 1958. Because of the risk of agranulocytosis, clozapine remained relatively obscure until the seminal study by Kane et al. [2] convincingly demonstrated its superior efficacy to chlorpromazine in treatment-resistant patients. Clozapine was reintroduced in the United States in 1990 under strict blood-monitoring requirements to mitigate the risk of agranulocytosis. Numerous studies have since confirmed its superior efficacy in patients with treatment-resistant schizophrenia [3, 4] and its broader spectrum of efficacy, including improvement in cognition [5], aggressivity [6], mood stabilization [7–9], and suicide risk reduction [10]. But perhaps the most important aspect of the clinical profile of clozapine is that it almost never causes parkinsonian-type side effects. For decades it was felt that the antipsychotic effect of antipsychotics and their propensity to induce parkinsonian-type side effects were inextricably linked; that is, to get an antipsychotic effect, it was necessary to increase the dose of the drug to the point of impairment of fine motor control. This, so-called neuroleptic threshold concept was essentially invalidated by the observed clinical profile of clozapine.

The “atypical” clinical profile of clozapine spurred the development of safer alternatives that would preserve the “atypicality” of clozapine and eliminate the agranulocytosis risk. The second-generation antipsychotics (SGAs), all introduced within the last decade or so, are also commonly referred to as atypical antipsychotics (risperidone, olanzapine, quetiapine, ziprasidone, and aripiprazole). Other agents not approved in the United States that have atypical properties include amisulpiride, zotepine, and sertindole (withdrawn from clinical use because of QT prolongation). Although there is debate as to what constitutes atypicality, the defining feature of this class of medications is the separation of the dose that results in a therapeutic effect from that which is associated with an increasing risk of EPSs. All SGAs meet this definition, but there are substantial differences in clinical profiles within the group. Unfortunately, the progress made in reducing motor side-effect burden with SGAs is tempered by their increased liability for causing weight gain (especially clozapine and olanzapine) and metabolic side effects, including increased risk of diabetes and dyslipidemia. The efficacy of these newer agents on psychotic symptoms has not been proven to be substantially different from conventional antipsychotics [11, 12], although one meta-analysis demonstrated a modest efficacy advantage for some of the SGAs [13]. The literature suggests incremental gains in cognitive function [14], relapse prevention [15–17], and negative symptoms [18, 19].

Despite the proven utility of antipsychotics in the management of schizophrenia, much remains to be deciphered about their differential clinical profiles, their mechanisms of action, and the pathophysiological substrates of the disease states in which they are used. In this chapter we will begin by briefly reviewing the two predominant theories of the proposed neurochemical dysregulation in schizophrenia; this will provide the conceptual framework for the rest of the chapter. We will then discuss and critique the various theories that attempt to explain the mechanism of action of antipsychotics, summarize the literature on their efficacy and side-effect profiles, and review strategies and targets for future drug development.

11.2 NEUROCHEMICAL HYPOTHESES OF SCHIZOPHRENIA

This review will cover the current status and the salient research relevant to the dopamine and glutamate dysfunction hypotheses of schizophrenia but is not meant to be an exhaustive review of the data. Readers are referred elsewhere for more detailed information [20–23; see also other chapters in this part].

11.2.1 Dopamine Hypothesis

The dopamine hypothesis of schizophrenia was proposed more than 40 years ago by Carlsson and Lindquist [24], who showed that haloperidol and chlorpromazine increased the turnover of brain monoamines as reflected by an increase in their metabolites. They proposed that these drugs acted on monoamine receptor targets in brain causing a secondary compensatory increase in monoamine turnover. Numerous studies have documented that dopamine-releasing drugs such as amphetamine are capable of inducing a paranoid psychotic state in normal control subjects that closely resembles paranoid schizophrenia [25, 26]. Additionally, psychotic symptoms are exacerbated in approximately 40% of schizophrenic patients after receiving smaller doses of such stimulants that are not psychotogenic in normals [27, 28]. Moreover, data suggest that patients who show such symptom exacerbation upon stimulant challenge are at increased risk for acute relapse if not taking antipsychotics [29–31]. In 1967 Van Rossum [32] was the first to hypothesize that the therapeutic effects of antipsychotics were related to their action on dopamine (DA) receptors. However, it was not until the mid 1970s that these receptors were actually identified and the actions of these drugs linked to D₂ receptors [33, 34]. Advances in functional brain-imaging [single-photon emission computerized tomography (SPECT) and positron emission tomography (PET)] technology in the past 20 years have provided in vivo evidence in support of the dopamine hypothesis, at least in the pathogenesis of psychotic symptoms.

Wong et al. [35] using [¹¹C]-*N*-methyl-spiperone were the first to study in vivo D₂ receptor density in the striatum of patients with schizophrenia and found a substantial elevation compared to normal control subjects. Most subsequent studies, however, failed to replicate this finding [23]. One factor frequently quoted as impacting the results in D₂ receptor quantification studies is the upregulation of these receptors following antipsychotic treatment, a fact well established in the animal literature. The usual drug-free period prior to imaging is two to three weeks, but it is not precisely known if this is enough time for complete reversal of

upregulation secondary to antipsychotic therapy. Other factors, such as small sample size, differences in receptor ligands used in different studies, and their susceptibility to competition from endogenous dopamine for the D_2 receptors, may also have contributed to these inconsistent results [23, 36, 37]. However, when all the PET and SPECT studies that have addressed this question are pooled, the effect size of increased D_2 receptor densities in schizophrenia was 0.51 ± 0.76 [standard deviation (SD)] [23]. The probability of yielding this effect size under the null hypothesis of “no difference” is <0.05 [23]. This translates to a 12% increase in D_2 receptor density parameters in patients with schizophrenia, an increase that is significant compared to controls, although not of the magnitude reported in postmortem studies [23].

The state of presynaptic DA synthesis in the striatum of patients with schizophrenia has also been investigated. Seven studies [38–44] have examined dopa-decarboxylase (a non-rate-limiting enzyme in the synthesis of DA) in patients with schizophrenia, and most demonstrated a higher accumulation of radioligand labeled 3,4-dihydroxy-L-phenylalanine (DOPA), suggestive of increased dopamine synthesis. Increased DA synthesis, however, does not necessarily imply increased DA release into the synapse. In a series of elegant experiments using SPECT and PET, Laruelle et al. [45] and Breier et al. [46] found that an intravenous amphetamine challenge in drug-naïve/drug-withdrawn patients with schizophrenia resulted in a greater *decrease* in radioligand binding relative to baseline as compared to normals, suggesting a relatively greater release of DA upon amphetamine stimulation in schizophrenia. As expected, the increase in DA release following amphetamine was associated with transient worsening of psychotic symptoms. Furthermore, the severity of baseline psychotic symptoms was correlated with baseline DA level as well as the magnitude of DA release upon amphetamine challenge and subsequent treatment response. However, the magnitude of DA release accounted for only 30% of the variability in the psychotic response [23]. Finally, higher challenge-induced DA release was found in most but not all patients in acute relapse and was not demonstrable in stable outpatients.

Although these seminal studies confirmed a dysregulation in the synaptic control of DA in at least some patients with schizophrenia in response to an exogenous pharmacological challenge, they did not provide information on the natural state of the DA synapse. Another productive strategy to indirectly assess intrasynaptic DA has utilized two PET studies to quantify D_2 receptor occupancy before and after two days of treatment with α -methylparatyrosine (AMPT), which acutely depletes DA; the extent of the *increase* in D_2 radioligand binding from baseline to post-AMPT treatment is an indirect quantitative measure of intrasynaptic DA concentration at baseline; that is, the greater the increase in D_2 binding following DA depletion, the greater the baseline occupancy of D_2 receptors by DA. Using this strategy in acutely relapsed medication-naïve or medication-free patients, Abi-Dargham et al. [47] found a statistically greater increase in D_2 binding following DA depletion in patients with schizophrenia compared to healthy age- and sex-matched controls. These observations suggest that in acute exacerbation schizophrenia is associated with higher intrasynaptic DA levels compared to normal controls. Psychotic symptoms improved upon DA depletion (cf. experience with reserpine in the 1950s), and the increase in radioligand binding in the striatum was correlated with the degree of improvement of psychotic symptoms. If these observations are confirmed, it would provide direct proof of the DA hypothesis that increased DA transmission is, at least in part,

responsible for psychotic symptoms [23]. It is important to reiterate that these conclusions of increased subcortical DA transmission in schizophrenia are based on group data and individual patients may fall within the normal range of DA transmission parameters.

Thus far we have focused on DA transmission indices in subcortical regions and their relation to psychosis. Another brain region implicated in the pathophysiology of schizophrenia, especially with regards to cognitive dysfunction and negative symptoms, is the dorsolateral prefrontal cortex (DLPFC) [48]. A few PET studies have examined the density of D₁ receptors in the prefrontal cortex (PFC), where this is the predominant DA receptor subtype. The results have been conflicting. Okubo et al. [49] demonstrated a *decrease* of D₁ receptors in the PFC, Abi-Dargham et al. [50] found an *increase* in D₁ receptors in the DLPFC, while Karlsson et al. [51] were unable to demonstrate a difference from normals in D₁ receptor density in any subcortical or neocortical region that was examined. Receptor ligand differences have been proposed as accounting for these discrepancies [52]. Interestingly, despite variable outcomes in D₁ receptor densities in the DLPFC in the above studies, all found an association between D₁ binding and various cognitive measures and/or negative symptoms. Potential D₁ receptor dysfunction is especially relevant for the pathophysiology of schizophrenia given the postulated role for this receptor in mediating critical aspects of cognitive function [53] and the ability of a full D₁-like agonist (ABT431) to reverse working memory deficits that emerge after long-term treatment with antipsychotics in nonhuman primates [54]. Functional brain-imaging studies in patients with schizophrenia have consistently demonstrated a hypometabolic state in the DLPFC which is correlated with poor performance on cognitive tasks and negative symptomatology [55].

Further support for DA dysfunction in the PFC comes from studies that have evaluated cognitive function in carriers of the valine allele of catechol-*O*-methyltransferase (COMT), an enzyme involved in DA degradation. This type of gene polymorphism increases the activity (methylation of dopamine) of COMT fourfold compared to the methionine allele, presumably resulting in lower functional DA levels in the PFC of people who carry the *Val* allele. Subjects with valine gene polymorphism demonstrate worse performance on cognitive tests of PFC function compared to the methionine allele carriers [56–59].

Thus, all these observations point in the direction that there is reduced DA function in the DLPFC of schizophrenia patients, although the exact nature of the pathophysiology underlying this perturbation (D₁ receptor dysregulation, decreased presynaptic DA release, excessive degradation of DA, or secondary to some other factor) is yet to be identified.

In summary, the literature reviewed above suggests, in its simplest form, that schizophrenia is associated with a functional *increase* in subcortical dopamine transmission which correlates with psychotic symptoms and is evident at illness onset and in acute exacerbation but not in stable outpatients, as well as a functional *decrease* in dopamine transmission in the PFC that appears to underlie deficits in cognition and negative symptomatology.

11.2.2 Glutamate (NMDA Receptor Hypofunction) Hypothesis

The second dominant pathophysiological hypothesis of schizophrenia is the glutamatergic dysfunction hypothesis. Glutamate acts on two families of receptors: ionotropic

receptors, which are rapid excitatory on–off cation channels, and metabotropic receptors, which are G-protein coupled. The ionotropic receptors are further subdivided into the kainate receptor, the α -amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptor, and the *N*-methyl-D-aspartate (NMDA) receptor. The NMDA receptor is equipped with an ion channel regulating the penetration of calcium and other cations into the neuron. PCP binds to a specific site in this channel, thereby blocking the function of the receptor. Glycine, a coagonist, binds to the strychnine-insensitive binding site and enables glutamate to open the ion channel.

The glutamatergic dysfunction hypothesis evolved from observations that phencyclidine (PCP), a noncompetitive antagonist at the NMDA receptor, could induce a psychotic state in normals that was accompanied by negative symptoms and cognitive deficits that were similar to those seen in patients with schizophrenia [60, 61]. Subanesthetic doses of another noncompetitive NMDA receptor antagonist, ketamine, have also been shown to faithfully induce the spectrum of psychopathology of schizophrenia when administered to normal control subjects [62, 63]. Jentsch and Roth [64] contend that long-term repeated exposure to PCP (as opposed to acute exposure) faithfully mimics the various abnormalities observed in patients with schizophrenia, including positive symptoms, negative symptoms, and cognitive dysfunction, as well as hypofrontality in cerebral blood flow in functional brain-imaging studies. Patients with schizophrenia were found to be more sensitive to the deleterious effects of ketamine and demonstrated a worsening of positive and negative symptoms and cognitive deficits [65–67]. These observations led to the hypothesis that NMDA receptor hypofunction might be involved in the pathophysiology of schizophrenia [62, 68–70]. Farber and colleagues have hypothesized that decreased functioning of NMDA receptors leads to reduced inhibitory output from γ -aminobutyric acid (GABA)–ergic interneurons and consequent increased cortical glutamatergic excitatory output to limbic regions leading to symptoms of schizophrenia. Consistent with the NMDA receptor hypofunction hypothesis is the observation that glutamatergic agonist drugs such as glycine and D-serine have shown promising results in treatment of patients with schizophrenia; these will be reviewed later. Lastly, postmortem studies have identified abnormalities of glutamate receptor density in the PFC, thalamus, and temporal lobe of patients with schizophrenia [71–73].

11.2.3 Integration of Dopamine and Glutamate Hypotheses

There is substantial evidence of reciprocal interactions between the glutamatergic and DA systems. Acute administration of ketamine to normal volunteers resulted in substantial increase in striatal DA release as measured by reduction in [^{11}C] raclopride binding using PET imaging [74–76]. Chronic NMDA receptor antagonist administration *increases* subcortical DA release, particularly in the nucleus accumbens, and *decreases* mesocortical DA transmission in animals [64]. Chronic administration of NMDA receptor antagonists also results in decreased expression of the DA D₁ receptor messenger RNA (mRNA) in the PFC of rats and monkeys [64, 77, 78]; as mentioned above, the D₁ receptor has been shown to be critical for working memory function [53].

Various possible disturbances in the corticostriatal–thalamic–cortical loops that connect the PFC to subcortical structures have been postulated to account for increased subcortical DA transmission in the context of reduced PFC activity and to

attempt to integrate the DA and glutamate dysfunction hypotheses (see [23] for a review and synthesis). Weinberger postulated in 1986 [79], based on the seminal work of Pycoc et al. [80], that dysregulation of subcortical DA function in schizophrenia may be secondary to a failure of the PFC to adequately inhibit subcortical transmission. Mesocortical DA input has the net effect of inhibiting subcortical DA release through feedback loops. This is mediated in part by DA stimulation of GABAergic interneurons in the cortex which inhibit excitatory glutamate corticostriatal input to ventral tegmental area (VTA) DA neurons. Reduced DA input to the PFC (or dysfunctional DA transmission in the PFC because of impaired D₁ receptor function) would result in increased excitatory glutamatergic output to VTA DA neurons and increased subcortical DA transmission.

A second mechanism proposed to account for increased subcortical DA transmission in the context of PFC dysfunction was proposed by Carlsson [81]. He described a model in which the PFC modulates subcortical DA transmission via an excitatory pathway (direct corticostriatal glutamatergic pathway) and an inhibitory pathway (indirect via intermediate midbrain GABAergic neurons), with the inhibitory pathway normally in slight dominance. Subtle NMDA receptor hypofunction would be predicted to result in reduced stimulation of the midbrain GABAergic interneurons (indirect pathway) which would normally inhibit the midbrain DA neurons. The release of VTA DA neurons from the normal inhibitory GABAergic input would result in increased subcortical DA transmission.

The third hypothesized mechanism of dysfunction in the corticostriatal–thalamic–cortical circuitry involves the GABAergic neurons in the PFC that exert tonic inhibitory control over excitatory glutamatergic projections to the VTA DA neurons. A primary deficiency in PFC GABAergic neurotransmission would release the glutamatergic corticostriatal neurons from inhibition and thereby directly stimulate VTA DA neurons into overactivity. Consistent with this proposed GABAergic functional deficiency are the results of several postmortem studies that demonstrate an alteration of GABAergic function in the PFC of patients with schizophrenia (reviewed in [23]).

The preceding brief conceptual overview of the neurochemical pathophysiology of schizophrenia highlights several possible strategies for targeting therapeutic interventions for this disorder. Psychotic symptoms, presumably secondary to increased subcortical DA transmission, could be addressed from several directions: by selective D₂ antagonism in limbic regions; by increasing DA transmission in the PFC (e.g., reducing the rate of DA degradation, increasing DA release, or blocking reuptake); by augmenting GABAergic action in the PFC; or by modulating NMDA receptor/glutamatergic function in the PFC. Negative symptoms and cognitive deficits may respond to interventions that increase PFC DA activity (by direct D₁ stimulation, reducing the rate of DA degradation, increasing DA release, or blocking reuptake). These strategies, of course, need not be mutually exclusive, and a combination of various interventions that target disturbed neural circuits at various points may provide *maximal* benefit to most patients and relief to those with treatment-resistant illness.

Finally, a disease as complex and clinically varied as schizophrenia is not likely to result from a simple dysregulation in one neurotransmitter system [82]. The variability in the exact nature and magnitude of the neural-based dysfunction in schizophrenia and its interaction with normal maturational/developmental brain processes [48], coupled with the variability inherent in the dynamic interaction of an

individual with his or her environment, are likely to collectively contribute to the clinical heterogeneity of the disorder across individuals and within the same individual in different stages (first episode vs. chronic) and phases (relapse vs. remission) of the illness. Whether schizophrenia is the result of a single insult that simultaneously disrupts the development and/or function of multiple neurotransmitter systems or neural circuits or the consequence of an insult that primarily disrupts one system with all other observed perturbations occurring secondarily as a compensatory response is not yet known. The precise answer to this question, however, may not be as pertinent to clinical progress as is a thorough understanding of normal brain circuitry and the homeostatic mechanisms that maintain stability among the various neural circuits which are the underpinnings of normal human emotion and cognition and how these homeostatic mechanisms are disrupted in schizophrenia. This knowledge will surely provide us with numerous opportunities to correct an imbalanced neural network(s) at multiple prospective loci irrespective of the exact nature and neuropathological location of the primary insult responsible for the disorder.

11.3 HYPOTHESIZED MECHANISMS OF ACTION OF ANTIPSYCHOTICS

We will begin with a review of the evidence in support of D₂ receptor antagonism of antipsychotics as the fundamental action that underlies their therapeutic effect on psychosis. We will then review the various theories that have been postulated to account for the atypical profile of SGAs and review the evidence for other receptor actions of antipsychotic drugs and how that may relate to their efficacy profiles.

11.3.1 D₂ Receptor Occupancy and Antipsychotic Effect

A consistent observation that has stood the test of time about antipsychotic drug treatment is that every clinically effective antipsychotic reduces DA transmission to some extent; drugs that do not have never been shown to have antipsychotic effect. More specifically, the primary receptor target implicated in antipsychotic effect, as well as the induction of EPS and prolactin elevation, is the D₂ receptor. Recent examples of non-D₂ antagonists that failed in clinical trials in schizophrenia are MDL-100907 [serotonin type 2A (5-HT_{2A}) antagonist] [83], L-745,870 (D₄ antagonist) [84], fananserin (5-HT_{2A} and D₄ antagonist) [85], and SCH-39166 and NNC-01-0687 (D₁ receptor antagonists) [86–88].

Dopamine receptors exist in two broad families, D₁-like (D₁ and D₅) and D₂-like (D_{2, long/short}, D₃, D₄). The D₁ receptor has widespread distribution and is the predominant DA receptor in the PFC, while the D₅ receptor is localized in specific corticolimbic regions. The D₂ receptor has both presynaptic (autoreceptor) and postsynaptic location, and its distribution is in mesostriatal–limbic regions; it also mediates prolactin release in the pituitary. The D₃ and D₄ receptors have low-density corticolimbic distribution, with the D₃ receptor additionally exhibiting presynaptic autoreceptor location (see [89] for review). Seeman [90] was the first to directly associate the therapeutic actions of antipsychotic drugs to the D₂ receptor. He demonstrated a strong correlation between in vitro affinities of antipsychotic drugs for the D₂ receptor and their clinical potencies [34], although at that time the various

subtypes of the D₂ family had not been identified. Recent studies, however, using cloned cell lines have confirmed that clinical antipsychotic potencies correlate generally with their affinities for the D₂ receptor expressed independently of D₃ and D₄ subtypes [90, 91].

The advent of functional brain-imaging techniques (SPECT and PET) in the late 1980s gave the opportunity to address in vivo the nature of the exact relationship between D₂ receptor occupancy and the three cardinal properties of FGAs: antipsychotic effect, EPS, and prolactin elevation. Farde et al. [92] using PET and [¹¹C] raclopride as the radiotracer, evaluated in vivo D₂ receptor occupancy by various FGAs and clozapine and found D₂ receptor occupancies in the range of 70–89% and 38–63% in FGA- and clozapine-treated patients, respectively. Patients who had acute EPSs had significantly higher D₂ receptor occupancies. Nordstrom et al. [93] confirmed that lower D₂ receptor occupancy was required for antipsychotic effect than for induction of EPS. Subsequently, Kapur et al. [94] confirmed in a low-dose haloperidol study in patients in first-episode schizophrenia that occupancy thresholds of 65, 72, and 78% were related to antipsychotic affect, prolactin elevation, and EPSs, respectively. These and other studies have found that there was a wide variation in D₂ receptor occupancy among patients on the same dose of drug and that the thresholds, although generally accurate, were not invariably reliable in predicting clinical events. For example, a few patients responded to FGAs at low D₂ occupancy, while other subjects with >65% D₂ occupancy did not exhibit a response [94–96]. Similarly, on occasion, occupancy >72% was not associated with prolactin elevation or occupancy >78% was not associated with EPS [94]. The D₂ receptor occupancy also did not correlate with improvement (or lack thereof) of negative symptoms or cognitive deficits. Despite these limitations of not accounting for *all* clinical scenarios observed in patients with schizophrenia, the importance of this work cannot be underestimated as these data directly link in vivo D₂ receptor occupancy to antipsychotic effect, prolactin elevation, and EPSs.

Another question that has recently been addressed in the literature is the time to onset of antipsychotic effect. It has been a long-held belief that onset of antipsychotic effect is delayed by one to two weeks after initiation of treatment, and “depolarization inactivation” of dopamine neurons which occurs over about a two-week time frame (see [97] for a review) has been proposed as the underlying mechanism responsible for this delay. Kuhar and Joyce [98] proposed that drug-induced changes in protein synthesis or degradation following changes in gene expression could also explain the delay. However, a recent article by Agid et al. [99] questions the very existence of the delay in onset of antipsychotic effect. They reported a meta-analysis of 42 double-blind comparator-controlled studies and found that antipsychotic effect was evident within the first week of treatment and improvement in the first two weeks was greater than during any subsequent two-week period. Kapur et al. [100] reported that onset of specific antipsychotic effect was evident within the first 24 h in a double-blind placebo-controlled study comparing intramuscular olanzapine to intramuscular haloperidol and that improvement in psychosis was independent of change in agitation and excitement. Abi-Dargham also observed rapid improvement in psychotic symptoms upon DA depletion with α -methyl-*para*-tyrosine [47]. These observations are intriguing and clearly warrant further investigation. If true, they again support a direct role for DA in the mediation of psychosis and antidopaminergic activity in antipsychotic effect.

With the introduction of the second-generation antipsychotics, functional brain-imaging techniques were used to address the question of the underlying mechanism of atypicality. That the level of D₂ receptor occupancy was important in atypicality had been suggested by the work of Farde in 1992 [92], in which clozapine demonstrated lower D₂ receptor occupancy as compared to FGAs.

Two major theories have been postulated to account for an atypical profile; relatively higher 5-HT_{2A} versus D₂ antagonism and relative ease of staying below the ~80% D₂ occupancy threshold for EPSs with SGAs because of their loose binding (lower affinity) to the D₂ receptor.

11.3.2 High 5-HT_{2A} versus D₂ affinity

Meltzer [101] (also see Chapter 12 by Meltzer) proposed that higher 5-HT_{2A} versus D₂ receptor affinity conferred an atypical profile. This was based on observations that a higher in vitro 5-HT_{2A} relative to D₂ affinity distinguished the atypical antipsychotic class. 5-HT_{2A} antagonism can increase DA transmission in the nigrostriatal pathway and thereby mitigate the risk of EPSs and may also contribute to improvement of negative symptoms and cognitive dysfunction by increasing DA release in the PFC [101]. However, there are critical limitations to the “serotonin/dopamine” theory of atypicality of SGAs (reviewed in [102]): many FGAs (chlorpromazine, loxapine) have high 5-HT_{2A} affinity [103] and do not have an atypical profile; amisulpiride has no appreciable affinity for the 5-HT_{2A} receptor, and aripiprazole has higher D₂ compared to 5-HT_{2A} affinity, and yet both have atypical profiles; risperidone and olanzapine demonstrate high 5-HT_{2A} receptor occupancy at doses that are not antipsychotic (therefore 5-HT_{2A} antagonism per se cannot account for antipsychotic effect), and as the dose of these drugs is increased beyond the usual therapeutic range, the risk of EPSs increases despite saturation of the 5-HT_{2A} receptor system; the relative ratios of 5-HT_{2A}/D₂ receptor affinities of the SGAs do not predict their clinical EPS liability, for example, risperidone has the highest and quetiapine the lowest 5-HT_{2A}/D₂ ratio, but most clinicians would concur (and the data show [11, 104, 105]) that the EPS liability of risperidone is greater than that of quetiapine. Additionally, at equivalent D₂ receptor occupancies, risperidone and haloperidol are associated with comparable EPS liability [106]. Thus, high 5-HT_{2A} affinity may contribute to modulating DA in the striatum and PFC, but high 5-HT_{2A} occupancy does not protect from EPSs if D₂ occupancy is greater than the EPS threshold. The 5-HT_{2A}/D₂ hypothesis therefore does not satisfactorily explain atypicality [107].

11.3.3 D₂ Occupancy Thresholds and Rapid Dissociation

The second major hypothesis put forth to account for atypicality is the loose binding, or low affinity, of SGAs for the D₂ receptor as compared to FGAs [108–110]. This builds on the observation by Farde and Nordstrom (see above) that higher D₂ receptor occupancy was observed with FGAs compared to clozapine and was correlated with increased risk of EPSs. PET imaging studies with SGAs have demonstrated that at clinically therapeutic doses these drugs occupy between 50 and 75% of D₂ receptors [92, 111–117]. On the other hand, FGAs occupy in excess of 75% of available D₂ receptors at therapeutic doses [92, 94]. Lower D₂ receptor

occupancy in and of itself would account for the lower EPS liability of SGAs if the proposed EPS threshold of $> \sim 80\%$ D_2 receptor occupancy is true. Kapur and Seeman [110], in a further elaboration of this concept, suggested that rapid dissociation of SGAs from the D_2 receptor is the fundamental underlying molecular property that accounts for atypicality. They propose that the most important aspect of the affinity of a drug for the D_2 receptor is not how rapidly it binds to a receptor but how rapidly it dissociates from that receptor. The rate at which a drug dissociates from the receptor, or its k_{off} , is the most important determinant of how the drug and DA compete for the receptor. In a unit of time, a drug with fast k_{off} goes on and off a receptor much more frequently than a drug with a slow k_{off} . The faster the k_{off} , the more quickly the drug responds to DA surges, allowing for a more physiological DA transmission [110]. They conclude that this relationship between fast k_{off} and low affinity is the critical underlying molecular feature that explains how low affinity at the D_2 receptor leads to the atypical antipsychotic profile.

Another feature of atypicality that is exhibited by all SGAs except risperidone and amisulpiride is minimal elevation of serum prolactin. However, prolactin elevation has been shown to occur with all SGAs, but for most, it is transient and rapidly returns to baseline several hours after the last dose [118]. This has also been attributed to rapid dissociation of SGAs (fast k_{off}) from D_2 receptors in the anterior pituitary. Risperidone-induced elevation of serum prolactin has been attributed, at least in part, to higher peripheral compared to central distribution of its active metabolite 9-OH risperidone, leading to excessive D_2 blockade in the anterior pituitary which lies outside the blood–brain barrier [102].

In terms of D_2 receptor occupancy profiles, clozapine and quetiapine differ from ziprasidone, risperidone, olanzapine, amisulpiride, and aripiprazole, as they never exceed approximately 60–70% D_2 receptor occupancy even at the highest therapeutic doses. Because these drugs rapidly dissociate from the D_2 receptor, the level of occupancy rapidly drops off after the last dose (300–600 mg/day quetiapine or 350 mg/day clozapine used in these studies) such that 12 h later it is only 20% for quetiapine and 55% for clozapine [113, 115, 119]. A possible downside of rapid dissociation of clozapine and quetiapine from D_2 receptors could be the rapid emergence of psychotic symptoms upon drug discontinuation [120]. Although initially ziprasidone was found to have substantial D_2 receptor occupancy at low doses (20- and 40-mg single doses) in healthy volunteers [121], a recent study [122] found that 60% D_2 occupancy was not achieved until plasma levels corresponding to a 120-mg/day dose were reached, suggesting the optimal dose of this drug is 120 mg/day or higher. The predicted dose based on PET imaging of ≥ 120 mg/day is consistent with the clinical trial data for this drug [123–125]. Risperidone and olanzapine demonstrate increasing D_2 occupancy with increasing dose and also are associated with dose-related risk of EPSs [126]. The only SGA that does not appear to fit into the D_2 threshold schema is aripiprazole, a mixed DA partial agonist/antagonist [127]. In a study of 15 healthy men [128] who were treated with aripiprazole for a duration of two weeks, it was found that a dose of 2 mg/day of aripiprazole occupied between 70 and 80% of the striatal D_2 -like DA receptors. When the dose was increased to 30 mg/day, the receptor occupancy increased to almost 95% in the putamen, yet no associated EPS was evident as would be predicted for all other antipsychotics based on the $> 80\%$ D_2 occupancy threshold. The lack of EPS with aripiprazole has been attributed to its agonist activity at D_2

receptors. Similarly, the lack of efficacy in the presence of adequate D₂ receptor occupancy at the 2 mg/day dose is also not consistent with the 65% threshold hypothesis of efficacy [127] and could be accounted for by the partial agonist activity of aripiprazole at the D-2 receptor.

Thus both the 5-HT_{2A}/D₂ and D₂ receptor occupancy threshold/rapid dissociation theories have limitations as to their ability to account for *all* aspects of the disease or clinical profiles of *all* antipsychotics. These limitations, however, do not diminish the tremendous contribution made by these hypotheses to our understanding of antipsychotic drug action and drug development.

11.3.4 Highly Selective D₂/D₃ Antagonism, D₄ Antagonism, and Regional Specificity

Amisulpiride is a unique antipsychotic in that it is a highly selective, low-affinity antagonist at D₂/D₃ receptors. It has no activity at the D₁ or any other receptor. Low doses of amisulpiride (50–100 mg/day) occupy only 4–26% of striatal D₂ receptors [129] and seem to improve negative symptoms [130], while higher doses of 200–800 mg/day occupy 38–76% of D₂ receptors [129] and are effective against both positive and negative symptoms [131, 132]. It has been hypothesized that at low doses amisulpiride preferentially antagonizes presynaptic D₂/D₃ receptors, causing an increase in DA transmission in the PFC accounting for its efficacy in negative symptoms [133].

Another property of some antipsychotics that has been proposed to account for an atypical profile is D₄ receptor antagonism. The D₄ hypothesis grew out of observations of the receptor binding profile of clozapine (D₄ affinity > D₂) and the localization of this receptor in corticolimbic regions. However, this hypothesis has not withstood the test of time, and a study of a D₄ receptor antagonists L-745,870 not only did not demonstrate antipsychotic efficacy or EPS but was associated with worsening compared to placebo [84]. Sonepiprazole, a selective D₄ antagonist, yielded a negative outcome in a large double-blind, placebo-controlled randomized trial in 467 inpatients with schizophrenia in acute relapse [134]. Fananserine, a mixed 5-HT_{2A} and D₄ antagonist, was also found to be without antipsychotic effect [85]. Also, quetiapine and amisulpiride do not have D₄ affinity but have an atypical profile [135, 136].

Regionally specific preferential binding of SGAs to DA tracts projecting to the limbic region (as opposed to motor striatal projections) has also been proposed as a mechanism contributing to an atypical profile. Numerous studies in animals have found a selective effect of SGAs on A10 versus A9 DA neurons and inducing early gene expression in the nucleus accumbens and medial striatum as opposed to the dorsolateral striatum [137–140]. In humans, several SPECT and PET studies have demonstrated this regional specificity for clozapine, risperidone, olanzapine, amisulpiride, quetiapine, and sertindole [112, 141–146], although other studies using more rigorous analytical methods [52] have found no regional specificity for clozapine or risperidone [147, 148]. Further evaluation of this attribute is required to confirm its existence in humans and identify its underpinnings; its significance is evident as it raises the possibility of spatial targeting of drugs in the future.

11.3.5 Role of D₁ Receptors and Other Mechanisms

Activity at other receptors has also been postulated to mediate antipsychotic or other effects of antipsychotics, such as improvement in mood, cognition, and negative

symptoms. As described in Section 11.2.1, the D_1 receptor in the PFC is critically important in working memory function. Long-term FGA treatment induced working memory deficits in nonhuman primates that were reversed by brief treatment with a full D_1 agonist, and the beneficial effects were maintained over an extended period of time [54]. As working memory deficits have been consistently documented in patients with schizophrenia [149], drugs that have D_1 agonist activity might be particularly useful to target such a deficiency. No currently available antipsychotic has D_1 agonist activity.

Preclinical studies suggest that 5-HT_{2A} antagonism in the presence of D_2 antagonism results in increased DA release in the PFC, an effect that might be mediated by 5-HT_{1A} agonism [150]. Aripiprazole, clozapine, ziprasidone, and quetiapine are all partial agonists at the 5-HT_{1A} receptor. Clozapine, olanzapine, risperidone, and ziprasidone, but not haloperidol, increased prefrontal DA release [151–153]. Irrespective of the exact mechanism, increased prefrontal DA release in the PFC with the SGAs might contribute to improvement in negative symptoms, depressive symptoms, and cognitive dysfunction. Most SGAs, but not the FGAs, also increase release of acetylcholine in the PFC, which might lead to improved cognitive function [154]. Ziprasidone is also a norepinephrine and 5-HT reuptake inhibitor, and since the norepinephrine transporter is also functional in DA reuptake in the PFC, it is possible that this is another mechanism by which ziprasidone may increase DA transmission in the PFC. Zotepine also inhibits norepinephrine reuptake.

Lastly, some of the SGAs, but not the FGAs, have been shown to modulate NMDA receptor function at the cellular and behavioral levels in preclinical animal models [155–159]. Clozapine and olanzapine, but not haloperidol or raclopride, inhibit the electrophysiological effects of PCP in brain slices [158, 160, 161] and attenuate NMDA receptor antagonist-induced deficits in prepulse inhibition [155, 162]. As these drugs do not directly interact with the glutamatergic system, it is not clearly understood how they might be exerting their influence. One possibility for clozapine was recently highlighted in the report by Sur et al. [163] which showed that the active metabolite of clozapine, *N*-desmethylozapine, can potentiate hippocampal NMDA currents by its M_1 agonist activity.

11.3.6 Synthesis

From the above review several preliminary conclusions can be drawn about the mechanisms of action of antipsychotic drugs and the basis of atypicality: (1) D_2 receptor antagonism is the fundamental property of antipsychotic drugs that underlies their antipsychotic effect; (2) continuous D_2 receptor antagonism is not required for antipsychotic effect, but how intermittent this antagonism can be without losing antipsychotic efficacy is not known; (3) different thresholds of D_2 receptor occupancy are predictive of antipsychotic effect, prolactin elevation, and EPS liability; (4) D_2 antagonism alone does not explain antipsychotic effect across all patients, that is, patients may fail to respond despite adequate D_2 blockade; (5) 5-HT_{2A} receptor antagonism and activity at other 5-HT receptors (e.g., 5-HT_{1A}) contributes to clinical profiles of most but not all SGAs (amisulpiride is an exception); (6) activity at receptors other than or in addition to DA receptors will probably be required for amelioration of negative symptoms, depressive symptoms, and cognitive dysfunction as well as for patients with treatment-resistant illness; and (7) there is substantial

variability among the SGAs in receptor binding and clinical profiles—they are not members of one class.

Lastly, on a cautionary note, although remarkable advances have been made in the neurosciences over the past two decades, it is important to guard against overinterpretation of findings about the mechanisms that underlie the antipsychotic effect. There are limitations to our current conceptualizations of the receptor or intracellular basis of efficacy and side effects of antipsychotics. Studies done at a cellular level clearly do not reflect what happens in intact neural circuits of living animals. As an illustration, the output of a neuron in an intact neural circuit in response to an input may be influenced by its basal activity state and what other stimulatory or inhibitory inputs it receives at that time—the same input may result in opposite outputs depending on these and other factors. Not surprisingly, conflicting or unexpected results are not uncommon when ideas generated from basic science are taken to behavioral animal models and then to human disease states. We also know that the same receptor type may mediate completely different actions at different locations in the brain, for example, the D_2 receptor mediating antipsychotic effect, EPSs, and influence over prolactin secretion. What makes these receptors behave differently in different brain regions is not exactly known, and will this knowledge, once it accumulates, be able to guide us in developing strategies for spatial targeting of drugs? Additionally, although the relationships between degree of receptor occupancy *in vivo* and clinical effect has received recent attention, the temporal component of this interaction has not been rigorously evaluated. Is it better (or worse) to occupy 50–60% of D_2 receptors for 20% of the time (quetiapine) or 60% of the receptors for 100% of the time (or any combination thereof)? As noted earlier, an occasional patient may improve at low D_2 receptor occupancies. A study by Nyberg et al. [164] found that D_2 receptor occupancy for patients taking monthly injections of haloperidol decanoate dropped from 73% (60–82%) at week 1 postinjection to 52% (20–74%) at week 4. Also, the 25-mg biweekly dose of the long-acting injectable formulation of risperidone demonstrated robust efficacy [165] but was associated with only 25–48% D_2 receptor occupancy at trough plasma levels at steady state [166]. Similarly, in the long-term outpatient trial of Fleischacker et al. [167], 25 mg biweekly was found to be an effective dose. These observations are compatible with several mutually nonexclusive scenarios: (a) that a substantially lower level of D_2 occupancy than the proposed ~65% threshold may be compatible with antipsychotic effect (at least in some patients); (b) that, similar to the profile of clozapine and quetiapine, D_2 receptor occupancy with long-acting injectables exceeds the antipsychotic threshold only transiently, although with these formulations the time frame during which the antipsychotic threshold is exceeded is in days (not hours) followed by several days of “subtherapeutic” D_2 receptor occupancy; and, lastly, (c) that a lower level of D_2 receptor occupancy may be sufficient for maintenance of antipsychotic effect as compared to the 60–70% postulated for treatment of acute exacerbation. The last scenario is consistent with the finding by Laruelle et al. [168] that stable patients (as opposed to those in acute relapse) did not exhibit abnormal DA release upon an amphetamine challenge; yet we know that patients remain vulnerable to relapse secondary to perturbation of the DA system in response to stress. These and other relevant clinical questions will need to be addressed over the coming years.

11.4 CLINICAL PROFILES OF ANTIPSYCHOTIC DRUGS

11.4.1 First-Generation or Conventional Antipsychotics

The FGAs (phenothiazines, butyrophenones, thioxanthines) had been the mainstay of treatment for psychotic disorders from the early 1950s until the introduction of the first-line SGAs in the early 1990s. Their primary efficacy domain is in psychotic symptoms and they demonstrate minimal efficacy against negative symptoms and cognitive dysfunction and may actually worsen depressive symptomatology [169, 170]. About a third of patients in acute exacerbation have minimal response to these medications, and another 50% have a partial response [171, 172]. There are no significant efficacy differences among FGAs (reviewed in [173]). Until recently, the only long-acting injectable formulations available were of the FGAs; risperidone is now available in a long-acting injectable form (Risperdal Consta). The FGAs were routinely used in doses that were excessive leading to high rates of movement disorders, secondary negative symptoms, and further cognitive impairment because of anticholinergic effect of the drug itself or the anticholinergics prescribed to mitigate EPSs. Their side-effect profile included acute EPSs, tardive dyskinesia (TD), neuroleptic malignant syndrome, sedation, anticholinergic side effects, weight gain, and prolactin-induced side effects. The rates of acute EPSs in first-episode patients at therapeutic doses were as high as 70% [174], while TD risk was approximately 5% per year of exposure in the not elderly [175] and 25–30% per year in the elderly [176]. The high risk of TD, a potentially irreversible movement disorder, and the high rates of acute EPSs were the major motivating factors for psychiatrists to switch patients to SGAs when they became available beginning in the early 1990s.

11.4.2 Second-Generation or Atypical Antipsychotics

There is a wealth of double-blind placebo- and active comparator-controlled studies of the SGAs, most of them conducted to obtain regulatory approval. Such studies, among others, have been included in several recently published meta-analyses [11–13, 177] of the efficacy and safety/tolerability of SGAs compared to FGAs and SGAs compared to each other. In general, these studies did not include treatment-resistant patients, were conducted mostly in patients in acute exacerbation, were of relatively short duration, and assessed limited efficacy and safety outcome measures. Also, since most of the studies in these meta-analyses were sponsored by manufacturers of the new agents, it can be safely stated that the designs were at best neutral and at worst stacked to favor the new agent. Usually these design flaws were reflected in a higher than necessary dose of the comparator FGA, which would be expected to negatively influence dropout rates (because of increased risk of side effects), negative and depressive symptom ratings (because of EPSs that may mimic negative/depressive symptoms), and cognitive function (because of higher use of adjunctive anticholinergic medication to ameliorate EPSs).

The first meta-analysis by Leucht [11] included studies on risperidone, olanzapine, quetiapine, and sertindole. They found a very modest efficacy advantage on total symptomatology for risperidone and olanzapine compared to haloperidol (effect size r values of 0.06 and 0.07, respectively), with no difference for quetiapine and sertindole. On negative symptoms both olanzapine and risperidone were superior

to haloperidol, but again the effect size was very small. Sertindole was no different from haloperidol in the treatment of negative symptoms, and quetiapine in one study [178] was equivalent to chlorpromazine while in another [105] it was actually statistically *inferior* to haloperidol. Compared to haloperidol, all SGAs were associated with lower anticholinergic use, although the effect was weakest for risperidone. Interestingly, in a double-blind sertindole study that used a low 4-mg/day dose of haloperidol there was still a statistically higher use of anticholinergic medication in this group of patients compared to pooled sertindole dose groups, suggesting that even at relatively low doses high-potency FGAs are associated with significant EPS liability [11]. In two studies that used either a midpotency or low-potency FGA comparator (perphenazine, chlorpromazine), no difference in concomitant anticholinergic use was found compared to the SGA group. Because of lack of efficacy, dropout rates were statistically lower only for olanzapine compared to haloperidol; olanzapine also demonstrated lower dropout rates because of adverse events. Quetiapine had lower dropout rates compared to haloperidol related to adverse events and did not differ in dropouts for lack of efficacy; risperidone did not show an advantage over haloperidol in dropout rates related to either lack of efficacy or adverse events. This meta-analysis therefore suggested minor efficacy advantages for olanzapine and risperidone, moderate overall tolerability advantage for quetiapine and olanzapine, and a lower EPS liability as reflected in lower anticholinergic use for all the SGAs compared to haloperidol. However, in a second meta-analysis by Leucht [177] comparing SGAs to only low-potency FGAs, no advantage on EPS liability was seen for the SGAs (other than clozapine), although a moderate superiority in efficacy was documented for the SGAs.

The meta-analysis by Geddes et al. [12] was even less optimistic. They included 52 randomized trials with a total of 12,649 patients treated with risperidone, clozapine, olanzapine, quetiapine, amisulpiride, and sertindole. Overall, they found that SGAs had slightly superior efficacy and better tolerability and a lower risk of causing EPSs. However, when they controlled for comparator dose of the FGAs and separately analyzed data for patients who received 12 mg/day of haloperidol equivalents or less, all advantages of SGAs except for a modest EPS advantage disappeared. Essentially the conclusion from this meta-analysis was that other than a slight superiority on EPS profile, all other differences in outcomes between SGAs and FGAs could be accounted for by a higher than necessary dose of the comparator FGA.

The last meta-analysis conducted by Davis et al. [13] included 124 randomized trials of 10 SGAs versus FGAs and 18 trials comparing different SGAs. They found significantly greater effect size for efficacy for clozapine (0.49), risperidone (0.25), olanzapine (0.21), and amisulpiride (0.29). The mean effect sizes for the above drugs (other than clozapine) corresponded to about a four- to six-point advantage on the PANSS compared to FGAs. For perspective, the difference between these SGAs and the FGA comparator group was about half as much further improvement over that seen with FGAs compared to placebo. The effect size of efficacy of clozapine versus FGAs was double that of other SGAs versus FGAs. Quetiapine, sertindole, ziprasidone, aripiprazole, and remoxipride demonstrated similar efficacy as FGAs. Significance for superior efficacy for zotepine depended on the statistical method used and was significant with one method and just missed significance with another. Distinct from the results of the Geddes meta-analysis, Davis et al. did not find that the dose of the comparator FGAs had any effect on the outcome of their

analysis. A sub-meta-analysis of studies comparing SGAs to each other did not reveal statistical differences among them on efficacy profiles. However, clozapine was superior to risperidone if studies that used a low dose of clozapine were excluded from the analysis. The Davis meta-analysis did not address safety and tolerability issues.

Thus, collectively these meta-analyses suggest an EPS advantage for the SGAs (although the dose of FGAs was higher than necessary in many studies and there were minor differences among the SGAs) and probable superior overall symptom efficacy for clozapine, risperidone, olanzapine, and amisulpiride over FGAs, with clozapine demonstrating the most robust difference.

The claimed superiority of SGAs over FGAs on negative symptoms is even more problematic to address, because some features of EPSs caused by FGAs (flat affect, bradykinesia—so-called *secondary* negative symptoms) may be impossible to distinguish from the *primary* negative symptoms of the disease [179–182]. Additionally, negative symptoms could also be secondary to positive symptoms, depressive symptoms, and environmental deprivation [183, 184]. Modest differences have been demonstrated for risperidone and olanzapine compared to FGAs [18, 19] on negative-symptom improvement using path-analytic methods that attempt to remove the influence of psychotic, depressive, and extrapyramidal symptoms on negative symptomatology. These results should not engender significant enthusiasm as the analyses were performed post hoc and the most effective dose of the SGA was chosen—the gain in negative-symptom improvement, most of it in secondary negative symptoms, is modest at best.

Similarly, the superiority of SGAs on cognitive function improvement relative to FGAs is not well established. Impairments in cognitive test performance in patients on FGAs may result from EPSs, anticholinergic effects, and sedative effects, on top of what is due to the underlying disease process [185–187]. The improvement seen in cognitive function with SGAs may at least in part be attributable to elimination or relative reduction of some of these deleterious effects of FGAs. Additionally, optimal dosing of FGAs is of critical importance in these studies as excessive dose may result in sedation and impairment of motor function secondary to EPSs that negatively impacts performance on timed tests. In general, the SGAs have demonstrated improvement in verbal fluency, digit symbol substitution, executive function, and fine motor control [5, 188], and a meta-analysis by Keefe et al. [189] found a significant overall advantage for SGAs on cognitive test performance. However, in a prospective two-year study Green et al. [190] found no advantage on cognitive functioning for risperidone (mean dose 6 mg/day) compared to haloperidol (mean dose 5 mg/day) in stable outpatients with schizophrenia. Similarly, a recent double-blind randomized 12-week trial [191] comparing olanzapine (mean dose 9.6 mg/day) with low-dose haloperidol (4.6 mg/day) found that both drugs improved verbal fluency, motor function, working memory, verbal memory, and vigilance to a similar degree in primary analysis. On secondary analysis, a minor advantage was noted for olanzapine, but statistical significance levels were not corrected for in multiple analyses that were conducted to yield this conclusion. Thus the differences in cognitive improvement with SGAs versus FGAs, if both are dosed appropriately, appear to be minor. Further research is needed to definitively address this issue.

The potential of some of the SGAs to delay relapse as compared to FGAs has also been evaluated. In a double-blind randomized trial comparing risperidone to

haloperidol and utilizing appropriate doses of both drugs, Csernansky et al. [192] found that risperidone was associated with a significantly lower risk for relapse by study endpoint (Kaplan-Meier estimates of relapse risk were 34 vs. 60%, respectively). Data are also available for olanzapine in maintaining long-term therapeutic effect [17]. The data from the extension phases of three double-blind studies comparing olanzapine to haloperidol were pooled to form one group for each drug. Olanzapine-treated subjects experienced less relapse ($p=0.034$), and the Kaplan-Meier estimated one-year risk of relapse was 19.7% with olanzapine and 28% with haloperidol. Finally, in a meta-analysis of relapse prevention studies comparing SGAs to FGAs conducted by Leucht [193], the rate of relapse and overall treatment failure were modestly but significantly lower with the newer drugs. Methodological limitations identified by the authors that need to be addressed in future relapse prevention studies included the choice of comparator FGA, use of appropriate doses, application of clinically relevant relapse criteria, and monitoring of adherence. Collectively, these data suggest that the SGAs are associated with a modest reduction in relapse risk, although methodological limitations of the studies conducted thus far dampen this conclusion.

The use of SGAs is now routine in the treatment of first-episode patients because of their lower EPS burden, slightly superior symptom domain efficacy, and probable superiority in relapse prevention. At a neurochemical level, SGAs, based on the evidence from animal literature, may have effects on the NMDA system that are different from those of FGAs (see Section 11.3), thus providing another avenue for assertion of therapeutic effect distinct from direct D_2 antagonism. If the pathophysiology of schizophrenia is progressive, modulation of the glutamatergic system by SGAs may lead to better long-term outcomes [194]. Two recent studies [16, 195] of olanzapine and risperidone in first-episode patients have demonstrated that in treatment of acute phase of the illness both drugs were comparable to haloperidol in efficacy. However, at the last observation point (12 weeks) in the olanzapine study, significantly more patients were still in treatment in the olanzapine arm versus the haloperidol arm (67 vs. 54%). Similarly, in the risperidone-versus-haloperidol trial, which used appropriate doses for both drugs (~ 3 mg/day), relapse rates were 42 and 55% for risperidone- and haloperidol-treated patients, respectively, over a median follow-up period of 206 days. Additionally, risperidone was associated with a significantly longer median time to relapse (466 days for risperidone- vs. 205 days for haloperidol-treated patients). The advantage for risperidone in reducing relapse risk was evident even though both groups had comparable symptom improvement. Both SGAs were superior to haloperidol in EPS liability; olanzapine caused more weight gain and risperidone more prolactin elevation compared to haloperidol. Weight gain was initially greater with risperidone compared to haloperidol, but at study endpoint there was no difference. These studies therefore support the use of SGAs in the first episode of the illness, not because of superior acute treatment efficacy but due to modestly better long-term relapse outcomes.

Another area of significant importance in schizophrenia treatment research is the study of the prodromal period preceding the onset of psychosis. The usual time from onset of frank psychotic symptoms to treatment initiation is one year, but when the prodromal period is taken into account, the average delay is three years [196]. There is widespread interest in evaluating the utility of various interventions in the

prodromal stage of schizophrenia before the onset of overt psychosis. The broad goals of these efforts are to develop systems for early recognition of psychosis in high-risk individuals and develop strategies for secondary prevention—specifically, does intervention during the prodromal period reduce the risk of developing overt psychotic symptomatology, and in those who do develop the illness, do these interventions alter the course or severity of the illness? Research in this area is in its early stages. McGorry et al. [197] reported on a randomized, controlled, nonblinded trial in 59 “ultra-high-risk” individuals at late prodromal stages close to psychosis onset. They compared low-dose risperidone treatment (mean dose 1.3 mg/day) combined with cognitive behavior therapy to routine clinical care over a six-month period followed by six months of needs-based care. Significantly fewer subjects in the risperidone group had transitioned into psychosis at the six-month time point, and in those subjects who had been compliant with risperidone, the benefits extended through the ensuing six-month extension period even though risperidone had been stopped. It is however not possible from this study to determine the relative contribution of risperidone or the cognitive behavior therapy to the reduced risk of transition into psychosis [197]. Early psychosis recognition and intervention programs are being developed in several countries and we await the results of this important work.

Lastly, in treatment-resistant schizophrenia the evidence in support of clozapine is most robust and it is the only antipsychotic specifically approved by the U.S. Food and Drug Administration (FDA) for this indication as well as for reduction of suicide risk. In a review of seven studies Chakos et al. [4] found clozapine to be superior in efficacy to FGAs, produced less EPSs, and was associated with better compliance. The double-blind, randomized, active comparator-controlled (olanzapine) study that led to the suicide risk reduction indication for clozapine [10] included 980 patients who were at relatively higher risk of suicide that were followed for up to two years. Approximately 25% of patients had treatment-resistant schizophrenia. Suicidal behavior was significantly less in patients treated with clozapine versus olanzapine as reflected by fewer clozapine-treated patients attempting suicide (34 vs. 55; $p=0.03$), requiring hospitalizations (82 vs. 107; $p=0.05$) or rescue interventions to prevent suicide (118 vs. 155; $p=0.01$), or requiring concomitant treatment with antidepressants (221 vs. 258; $p=0.01$) or anxiolytics or soporifics (301 vs. 331; $p=0.03$). Clozapine remains a uniquely effective drug, especially for treatment-resistant schizophrenia, and its importance to contemporary antipsychotic research is evident in the fact that all theories of the neurochemical underpinnings of atypicality evolved from observations and research on its biochemical and clinical profiles.

11.4.3 Safety and Tolerability

The biggest advance in side-effect profiles of SGAs is the lower risk of acute EPSs. Among the types of EPSs, acute dystonias are very rare with SGAs, while akathisia still occurs with all the newer agents. Within the group, clozapine and quetiapine have the lowest (almost absent risk) of parkinsonism, while amisulpiride, risperidone, and olanzapine are associated with dose-related parkinsonism. Ziprasidone and aripiprazole can also occasionally induce EPSs, although it is not clear if there is a dose relationship with these drugs. Lower rates of TD have also been reported

with risperidone compared to haloperidol (0.6 vs. 4.1%, respectively) in a one-year double-blind study [192] and for olanzapine compared to haloperidol (0.5 vs. 7.4%, respectively) [198]. Weight gain has emerged as a major problem with some of the SGAs [199]. Olanzapine and clozapine are most notorious in this respect, and in some patients, rapid and massive weight gain can occur. Quetiapine and risperidone are intermediate in weight gain liability, while ziprasidone and aripiprazole rarely cause significant weight gain [200]. Weight gain in patients with schizophrenia is especially problematic as these patients are usually overweight at baseline, have high rates of smoking, and are usually physically inactive. This combination of risk factors topped off by an increased risk of glucose dysregulation and hyperlipidemia reported to varying degrees with these agents [200] can create a potentially fatal constellation of risk factors for cardiovascular disease and stroke. These adverse effects in their entirety may well be worse than tardive dyskinesia, which was the major concern for FGAs [201]. The diabetes risk appears to be greatest for clozapine and olanzapine, less for risperidone and quetiapine, and lowest for ziprasidone and aripiprazole [200]. Risperidone causes sustained prolactin elevation, and therefore patients who previously developed prolactin-induced side effects (galactorrhea, gynecomastia, menstrual irregularities, and sexual dysfunction) on older agents should be tried on other SGAs. Ziprasidone is associated with QT prolongation, although the significance of this in patients with no other risk factors is not clear. Clozapine, in addition to agranulocytosis risk and other side effects mentioned previously, is associated with significant orthostasis, seizures (dose related), myocarditis, constipation (at times severe), and various other side effects, making it a challenging drug to use in clinical practice. Recently, the FDA issued a black-boxed warning of increased death rate in elderly patients with dementia who were prescribed SGAs. This was based on a review of data from 17 placebo-controlled trials of SGAs (risperidone, olanzapine, aripiprazole, quetiapine) involving 5106 elderly patients with dementia-related psychosis. The results showed an approximate 1.6-fold increase in death rate with SGAs compared to placebo. The warning is applicable to all SGAs marketed in the United States. No controlled data are available for FGAs as regards to this risk. Additionally, from the same studies, an increased risk of stroke and other cerebrovascular adverse events were noted for risperidone, olanzapine, and aripiprazole (approximately 2–3 times greater rate of these events in drug vs. placebo). Data were not available for the other SGAs.

In summary, incremental gains have been made with the SGAs in terms of efficacy, but clozapine still remains unchallenged in its robust efficacy profile, especially in treatment-resistant patients. Significant reduction in the EPS burden with SGAs, however, is offset by problematic side effects of weight gain, diabetes, and hyperlipidemia.

11.5 DRUGS IN DEVELOPMENT AND FUTURE DIRECTIONS

This section will review drugs that are currently in clinical development or in preclinical evaluation as well as potential future interventional targets, some of which are relatively speculative at this time.

11.5.1 Drugs Acting Directly or Indirectly on Dopamine System

Asenapine is a 5-HT_{2A}/D₂ antagonist that is being jointly developed by Pfizer and Organon and is in phase III clinical trials. Early data from previous trials show good tolerability and superior efficacy when tested against a placebo. No information is available in the public domain about the nature or the methods of the study.

Bifeprunox is in phase III clinical trials. It is a partial DA agonist/antagonist as well as a 5-HT_{1A} receptor agonist. Early results report little to no weight gain and no cardiac or EPS effects. No further information is available.

Iloperidone is being developed by Titan Pharmaceuticals (currently in phase III FDA clinical trials) after being dropped by Novartis due to concerns that the drug may increase the QT interval. Iloperidone displays high affinity for norepinephrine α_1 adrenoceptors and DA D₃ and 5-HT_{2A} receptors and intermediate affinity for norepinephrine α_{2C} adrenoceptors and DA D₂ and D₄ and 5-HT_{1A}, 5-HT_{1B}, 5-HT_{2C}, and 5-HT₆ receptors [202]. This broad receptor profile makes it an interesting drug, although it has been in development for more than 10 years. In patients with schizophrenia treated with iloperidone, a low incidence of EPSs and weight gain has been shown. Data from phase II trials demonstrated efficacy in patients at doses of 8 mg/day and tolerability was good up to 32 mg/day [203].

Paliperidone extended release is the active metabolite (9-OH risperidone) of risperidone. It is a 5-HT_{2A}/D₂ antagonist and is being developed by Johnson and Johnson. No specific research information was found on this compound.

Ocaperidone has approximately equivalent antagonism of 5-HT_{2A} and D₂ DA receptors. It is nearing the end of phase II clinical trials.

Modafinil, a drug currently used to treat narcolepsy, is now being examined for its potential to improve cognitive symptoms and working memory in schizophrenia patients. The mechanism of action is still not entirely clear, although it appears that modafinil induces wakefulness through activation of sleep/wake centers in the hypothalamus and increases DA levels in the PFC. Turner [204] studied 20 chronic schizophrenic patients in a double-blind, randomized, placebo-controlled crossover study using a 200-mg dose of modafinil. Improvement was seen on short-term verbal memory span, with trends toward improved visual memory and spatial planning. This was accompanied by reduced response latency on the spatial planning task. Significant improvement in attentional set shifting was seen in schizophrenic patients, despite no effect of modafinil being seen in healthy volunteers or attention-deficit hyperactivity disorder (ADHD) patients on this task. Modafinil is currently in phase II clinical trials to test whether it improves working memory in schizophrenia patients with COMT gene variations.

Tolcapone is a COMT reversible inhibitor that acts in the PFC of the brain. By inhibiting the catabolism of DA it may be beneficial for the cognitive deficits associated with schizophrenia, especially working memory. Its measurable effects in rat brains include an increase in DA neurotransmitter levels in the PFC but not in the striatum [205], and it has been shown to improve cognitive dysfunction in advanced Parkinson's disease [206]. It can cause severe liver dysfunction and has been removed from the market in several countries. It is currently being evaluated in a National Institute of Mental Health (NIMH) placebo-controlled trial in patients with schizophrenia and normal controls with and without the high-risk COMT alleles.

11.5.2 D₄ Antagonists

The negative studies for the highly selective D₄ antagonist L-745,870 [84], the 5-HT_{2A}/D₄ antagonist finanserin [85], and sonepiprazole [134] were described earlier. The D₄ story does not look optimistic, at least in monotherapy.

11.5.3 D₃ Antagonist

The D₃ receptor has corticolimbic distribution and is of interest because most antipsychotics have high affinity for this receptor [207]. In a postmortem study of schizophrenia, D₃ receptors were increased in the limbic striatum of drug-free patients, while it was normal in those treated with antipsychotics [208]. D₃ antagonists have been developed (S33084, SB-277011-A, AVE5997), but there are only limited animal behavioral data at this time. Controlled trials of D₃ antagonists will help clarify the differential contributions of the D₂ and D₃ receptor in the mediation of antipsychotic effect.

11.5.4 D₁ Agonists and Antagonists

The relevance of this receptor to cognitive function was covered earlier in the chapter. In the early 1990s there was interest in D₁ receptor antagonists as possible antipsychotic agents because they were active in preclinical models predictive of antipsychotic effect [91]. However, clinical trials of SCH-39166 [86, 87] and NNC-01-0687 [88] demonstrated no antipsychotic activity. On the other hand, there is substantial interest in D₁ agonists for their potential role in cognitive enhancement, and positive results have been obtained in nonhuman primates [54]. DAR 0100 (dihydroxidine) is a high-affinity short-acting D₁ agonist that has been studied in Parkinson's disease [209] and is currently being tested as a treatment for cognitive deficits in schizophrenia.

11.5.5 Neurotensin Agonist/Antagonist

Neurotensin, an endogenous neuropeptide, is colocalized with DA neurons that project specifically to the PFC and nucleus accumbens and it acts as a modulator of DA function [210]. Neurotensin was proposed to have potential antipsychotic activity more than two decades ago [211] (see [212] for a review). The problem with developing neurotensin agonist/antagonists is their rapid degradation by peptidases and difficulty crossing the blood–brain barrier. Centrally administered neurotensin demonstrates behavioral and biochemical effects very similar to antipsychotics [213]. A recent placebo- and haloperidol-controlled randomized trial to evaluate the utility of four potential novel agents in the treatment of schizophrenia included the neurotensin (NTS1) antagonist SR 48692 as one of the agents [214]. It did not demonstrate any therapeutic effect. However, it has been proposed that neurotensin *agonists* may be more relevant to the treatment of schizophrenia [215]. Richelson et al. [215] have developed a neurotensin agonist, (2*s*)-2-amino-3-(1*H*-4-indoyl) propanoic acid, that is resistant to peptidases and enters the brain if injected outside the brain. It is currently in preclinical toxicology testing.

11.5.6 Neurokinin Antagonists

Neurokinin 3 (NK3) receptors appear to regulate midbrain DA activity [216, 217]. A NK3 antagonist in development as potential treatment for schizophrenia is osanetant [218]. In the study of four novel compounds referred to above, Meltzer et al. [214] found that patients treated with SR 142801 demonstrated significant global and psychotic symptom improvement, though not of the same magnitude seen in the haloperidol group.

11.5.7 Drugs Acting on Glutamate System

If NMDA receptor hypofunction contributes to the pathophysiology of schizophrenia, then drugs that enhance NMDA receptor function could potentially be useful in the treatment of this disorder. Various strategies are being employed to modulate the glutamatergic system. Glycine is an obligatory coagonist at the NMDA receptor, and this site represents an interesting target for NMDA receptor augmentation. Studies with glycine have yielded mixed results with very high dose studies showing some benefit (see [20] for a review). This probably results from poor brain penetration of glycine. More optimistic results have been obtained with the glycine site agonists D-cycloserine and D-serine when they are added to ongoing antipsychotic treatment (except when added to clozapine). Patients demonstrated improvement in negative and cognitive symptoms, but less so on positive and depressive symptomatology. D-Serine appears to be the most promising as it has better permeability at the blood–brain barrier than glycine and does not have the partial agonist properties of D-cycloserine. In an eight-week add-on trial of D-serine in treatment-resistant patients with schizophrenia, D-serine treatment was associated with improvement in negative, cognitive, and positive symptomatology [219]. In the first systematic review and meta-analysis of glutamatergic drugs for schizophrenia, Tuominen [220] found a beneficial treatment effect on negative symptoms of schizophrenia only for add-on treatment with glycine and D-serine. The average improvement on the PANSS-negative subscale was a modest four points. There was also a trend toward positive effect on cognitive symptoms for glycine and D-serine, although further trials are needed to confirm this finding [220]. In this review D-cycloserine was not found to be helpful in schizophrenia and may even have been detrimental.

Another approach to augmentation of glycine at the NMDA receptor is to inhibit its reuptake, thereby increasing intrasynaptic concentration of glycine. A couple of glycine transporter inhibitors (sarcosine, glycyldodecylamide) show some potential in animal models for antipsychotic effect [221–224]. In a recent six-week double-blind, placebo-controlled add-on trial of sarcosine for the treatment of schizophrenia, significant improvement in positive, negative, and cognitive symptoms was evident in the sarcosine group [225].

Glutamate reuptake inhibitors can control glutamatergic transmission by removal of glutamate from the synapse. Postmortem studies in schizophrenia have revealed alterations in gene expression of glutamate transporters [226, 227]. Theoretically glutamate reuptake inhibitors could have potential utility in schizophrenia, although no such agent is currently in testing.

There is also interest in group II metabotropic glutamate receptors (mGluR2/3) which are presynaptically located and may function as autoreceptors regulating

glutamate release [228, 229]. Inconsistent results in behavioral animal models have been obtained thus far with mGluR2/3 agonists ([229]). However, in a preliminary human trial in normal subjects, the mGluR2/3 agonist LY354740 attenuated ketamine-induced working memory impairment [230].

The non-NMDA ionotropic glutamate receptors, AMPA, and kainate receptors could potentially mediate some of the behavioral effects of increased glutamate release seen following NMDA antagonism with drugs such as ketamine. Antagonists at these receptors have been shown to reverse some of the deficits induced by NMDA antagonism in pharmacological and behavioral animal models [231–234]. These data suggest that AMPA/kainate receptor antagonists could potentially have utility for the treatment of cognitive deficits [231]. In contrast to the agents discussed above, ampakines *augment* AMPA receptor function and enhance long-term potentiation, learning, and memory in rodents [235, 236]. It is suggested [20] that ampakines, by potentiating AMPA receptor-induced depolarization, indirectly enhance NMDA receptor function. CX516, the first member of this class, synergistically blocked methamphetamine-induced rearing behavior in rats when it was added to clozapine and to conventional antipsychotic agents, an effect believed to predict antipsychotic efficacy [237]. In preliminary human trials in patients with schizophrenia, CX516 improved cognitive and negative symptoms in patients who were also taking clozapine [238]. However, in a recent double-blind, placebo-controlled small study of patients with schizophrenia who were partially refractory to treatment with FGAs, CX516 in monotherapy did not produce impressive effects on positive and cognitive symptoms [239].

Memantine is a noncompetitive NMDA receptor antagonist. Although speculative, it is possible that memantine, by antagonizing NMDA receptors on GABAergic interneurons in the PFC, could potentially reduce the GABAergic (inhibitory) input to the glutamatergic neurons resulting in an increased glutamatergic output. Forrest Pharmaceuticals is currently sponsoring a phase II double-blind, placebo-controlled efficacy and safety trial of memantine added on to atypical antipsychotics in patients with schizophrenia.

Lamotrigine added to ongoing antipsychotic treatment has yielded some positive outcomes. Kremer et al. [240] conducted a 10-week, double-blind, placebo-controlled study in 38 treatment-resistant schizophrenia inpatients receiving conventional and atypical antipsychotics. Patients were randomized in a 2 : 1 ratio to receive adjuvant treatment with lamotrigine, gradually titrated to a 400-mg/day dose, or placebo. Of these, 31 completed the trial. In primary last observation carried forward analysis, no statistically significant between-group differences were observed; however, completer analyses revealed that lamotrigine treatment resulted in significant reductions in positive and general psychopathology symptoms; no significant differences in lamotrigine effects were noted between conventional versus atypical antipsychotics. In a double-blind, placebo-controlled add-on crossover trial involving 34 hospitalized treatment-resistant patients on clozapine Tiihonen [241] found that 200 mg/day lamotrigine was effective in reducing positive and general psychopathological symptoms, whereas no improvement was observed in negative symptoms. The positive impact of lamotrigine on psychotic symptoms may be mediated by DA modulation. Lamotrigine has been demonstrated to reduce DA levels in the striatum of mice presumably by inhibition of tyrosine hydroxylase, thereby reducing DA synthesis [242]. Lamotrigine also reduces glutamate release and in a controlled study

of normal volunteers was shown to reduce the extent of neuropsychiatric disruptions in response to ketamine [243]. Lamotrigine is now in phase III clinical trials as an adjunctive treatment for schizophrenia.

11.5.8 Noradrenergic Agents

Norepinephrine plays an important role in cognition in the PFC mediated by α_2 receptors [244–248]. The α_2 agonist clonidine has been shown to improve PFC-mediated cognitive function in patients with schizophrenia [249]. Guanfacine, a selective α_2 agonist, when added to risperidone or FGAs in a four-week placebo-controlled trial, resulted in significant improvement in tasks of working memory and attention, but only in the risperidone-treated subjects [250]. Thus, α_2 agonism may mediate improvement in some aspects of the cognitive function in schizophrenia. On the other hand, clozapine and risperidone are potent α_2 antagonists. Litman et al. [251, 252] reported that the addition of idazoxan, an α_2 antagonist to FGAs produced a “clozapine-like” profile. Antagonism at the α_2 receptors therefore, may contribute to the “antipsychotic” efficacy profile of antipsychotics.

11.5.9 Cholinergic Agents

The α_7 nicotinic acetylcholine receptor (nAChR) modulates auditory gating and has been shown to be reduced in certain brain regions of patients with schizophrenia in postmortem studies, and genetic studies link the α_7 nAChR gene to sensory processing deficits in schizophrenia (reviewed in [253]). Agonists at the α_7 nAChR are in development for clinical trials in schizophrenia.

The $\alpha_4\text{-}\beta_2$ nAChR represents more than 90% of the high-affinity nicotinic binding sites in the rat brain and is believed to play an important role in the actions of nicotine. SIB-1553A is an agonist at this receptor that appears to enhance performance in spatial and nonspatial working memory and reference memory in aged rodents and monkeys [254, 255]. These observations make $\alpha_4\text{-}\beta_2$ nAChR agonists interesting candidates for evaluation in the treatment of cognitive dysfunction in schizophrenia.

Galantamine is a positive allosteric modulator of nAChRs and also an acetylcholinesterase inhibitor. The allosteric interaction essentially amplifies the action of acetylcholine at pre- and postsynaptic nicotinic receptors. Presynaptic nAChRs are capable of modulating the release of acetylcholine, glutamate, GABA, and 5-HT. Case reports suggest that adjuvant galantamine improves negative symptoms in schizophrenia [256, 257]. An exploratory phase II study of galantamine in patients with schizophrenia who were smokers was recently completed in Canada. The results are not yet known.

A recent double-blind trial of donepezil, a reversible acetylcholinesterase inhibitor, did not show any positive effect when added to risperidone on cognitive function associated with schizophrenia [258].

Lastly, it is well known that cholinergic muscarinic receptors modulate dopaminergic and glutamatergic neurons (reviewed in [259]). Recently the *N*-desmethyl metabolite of clozapine was found to have potent partial agonist activity at this receptor, and it was demonstrated that it could potentiate NMDA currents in the hippocampus [163]. Examples of M_1 agonists include xanomeline and the M_2/M_4

agonists PTAC and BuTAC (reviewed in [259]). Xanomeline has been shown to have positive effects on cognitive and psychotic symptoms in Alzheimer's disease patients. Accumulating data suggest that muscarinic partial agonists might be efficacious in treating not only positive but also negative and cognitive symptoms of schizophrenia.

11.5.10 Other Agents

Acute cannabis intoxication can produce schizophrenia-like symptoms [260] and long-term use may induce "negative" symptoms [261]. These and other observations have led to a cannabinoid hypothesis of schizophrenia [262]. A cannabinoid CB1 antagonist (SR141716) recently failed to reveal any therapeutic effects in the four-novel-compound double-blind, placebo- and haloperidol-controlled six-week study of Meltzer et al. [214].

Other attempts at increasing dopamine in the PFC have included double-blind augmentation trials of the monoamine oxidase type B (MAO_B) inhibitor selegiline [263] and DA reuptake blocker mazindol [264], both of which did not yield a positive outcome on the primary outcome measure of improvement of negative symptoms.

Neurosteroids such as dehydroepiandrosterone (DHEA) and its sulfate derivative (DHEA-S) have demonstrated positive outcomes in case reports [265–267] and one double-blind study [268] as an adjunct to antipsychotic treatment, with improvement in negative, depressive, and anxiety symptoms, especially in women. Further studies with these and other neurosteroids are ongoing.

11.6 CONCLUSION

The last 15 years have been a period of rapid advance in our knowledge about the pathophysiology of schizophrenia, the mechanisms of actions of our drugs, and the number of potential therapies that are in development. An important area that was not covered here is pharmacogenomics (see [269, 270]) in which the relationships between specific genetic polymorphisms and the pharmacokinetic, pharmacodynamic, and clinical profiles of a drug are identified in populations of patients. This line of research will allow a more precise matching of patients with the drugs that they are more likely to respond to and/or better tolerate. At this time, we do not have reliable objective predictors of drug response or side-effect vulnerability.

Schizophrenia is a disease of multiple symptom domains and tremendous inter individual variability in clinical presentation and course. Currently we treat patients with one type of medication which is effective primarily against psychotic symptoms. As we get effective treatments for negative symptoms and cognitive dysfunction, it will likely be routine for a patient to be treated with a combination of drugs individually targeting the specific domains of psychopathology in that individual. The treatments for acute-phase illness will likely be different from maintenance strategies, either qualitatively or quantitatively.

Lastly, we are already moving beyond receptor pharmacology to the exploration of intracellular mechanisms of signal transduction, signaling pathways, and the factors that influence gene expression. Eventually, a thorough understanding of the factors that underlie cell development, plasticity, and resilience may enable us to develop entirely new classes of pharmacotherapeutic agents that exert their effects

intracellularly, and we may ultimately be able to stop deterioration and even reverse cumulative morbidity in schizophrenia, the most disabling of mental illnesses.

12.1 INTRODUCTION: DISTINCTION BETWEEN TYPICAL AND ATYPICAL ANTIPSYCHOTIC DRUGS

Antipsychotic drugs (APDs), by definition, suppress hallucinations and delusions, which are core features of schizophrenia as well as other neuropsychiatric disorders with psychotic features. Those APDs which produce catalepsy in rodents and extrapyramidal side effects (EPSs) in humans within the same dose range (e.g.,

chlorpromazine and haloperidol) are called typical APDs or neuroleptics. Acute EPSs (parkinsonism, dystonias, neuroleptic malignant syndrome) and delayed EPSs (tardive dyskinesia, tardive dystonia) represent disturbing and sometimes life-threatening side effects which interfere greatly with the patient's quality of life and compliance with treatment. Clozapine, discovered five years after chlorpromazine, was the first APD which did not produce catalepsy and virtually no EPSs. Because of this dissociation between antipsychotic efficacy and EPSs, clozapine was called an *atypical* APD. This name has persisted, although some clinical investigators incorrectly refer to typical APDs as first-generation antipsychotics and to clozapine and all subsequent atypical APDs as second-generation antipsychotics, even though many typical APDs which are still in use were discovered and introduced 5–10 years after clozapine (e.g., molindone and thiothixene) [1].

As will be discussed, there are important clinical differences between typical and atypical APDs beyond EPS liability. Clozapine (but not all other atypical APDs) was found to be effective to treat delusions and hallucinations in 60–70% of the 30% of patients with schizophrenia who have persistent psychotic symptoms despite treatment with typical APDs [2, 3] or with other atypical APDs [4]. Clozapine produces agranulocytosis in about 1% of patients [5]. For this reason, it has generally been used only in patients who do not respond to or cannot tolerate other APDs [3]. Atypical APDs are also able to modestly improve negative symptoms compared with typical APDs [6]. The advantage for efficacy for some atypical APDs over typical APDs has recently been challenged in a large, pragmatic clinical trial that had fewer constraints on patient population than most previous studies [7]. Most importantly, they have been reported to improve some domains of cognition in patients with schizophrenia [8, 9]. However, the advantages for cognition are modest, not apparent in all domains, and further research is needed to establish definitively that they do have an advantage over typical neuroleptic drugs to improve cognition. The advantage of greater efficacy for these components of schizophrenia coupled with advantages for EPS, both acute and chronic (e.g., tardive dyskinesia), has led to this group of compounds becoming the most widely prescribed APDs in all countries where they are freely available.

There are now numerous types of atypical APDs. As indicated in Table 12.1, there are at least seven subtypes of atypical APDs which have been identified, although not all are clinically available and, indeed, the efficacy of some of these agents is still not adequately established. In addition, there are many other proposed atypical APD mechanisms which cannot be reviewed here for space limitations.

As can be seen in Table 12.1, there is a diversity of mechanisms which are now believed to be able to achieve some degree of control of psychosis with significant sparing of EPSs. This review will consider current information on the mechanism of action of these drugs, concentrating on clozapine and related drugs because most is known about its actions.

12.2 CLOZAPINE AND RELATED DRUGS: DOPAMINE D₂ RECEPTOR BLOCKADE

There are numerous theories of why clozapine is atypical, that is, produces low EPSs at clinically effective doses. Historically, the low EPSs due to clozapine were

attributed to its relatively weak affinity for the D₂ receptor, its antimuscarinic properties, its lack of effect on the firing of nigro striatal dopamine (DA) neurons compared to ventral tegmental (VTA) DA neurons, or to D₁ receptor antagonism (see [10, 11] for a review). The typical APDs have been suggested to diminish psychotic symptoms by blockade of D₂ receptors in mesolimbic nuclei, especially the nucleus accumbens (NAC), stria terminalis, and extended amygdala, while blockade of D₂ receptors in the caudate/putamen (dorsal striatum) has been shown to be the

major basis for parkinsonism and other EPSs (see [10] for review). For the typical APDs, there is a very high correlation between the estimated therapeutic dose of these drugs and their affinity for the D₂ receptor [12, 13]. Actions of these agents at other receptors (e.g., M₁ muscarinic receptors, histamine H₁ receptors, and α_1 and α_2 adrenoceptors) have been thought to contribute to side effects such as drowsiness, weight gain, and constipation rather than efficacy.

Positron emission tomography (PET) studies utilizing ¹¹C-raclopride as the ligand have shown that occupancy of 65–80% of striatal D₂ receptors is required for an antipsychotic action by typical APDs and risperidone or olanzapine and that $\geq 80\%$ occupancy is associated with EPSs (see [14, 15] for a review). However, clozapine and quetiapine are effective at lower occupancies of D₂ receptors than typical and other atypical APDs listed with it in Table 12.1 (e.g., risperidone, olanzapine, and ziprasidone), implying some mechanism other than D₂ receptor blockade is contributing to their low-side-effect profile and perhaps their efficacy as well [14, 16–19]. However, caution is needed in interpreting these studies because they do not assess the occupancy of VTA, ventral striatal, or cortical D₂ receptors, all of which are more likely to be related to antipsychotic action than is the dorsal striatum, which is the region of interest in studies using ¹¹C-raclopride in the first generation of PET studies. This ligand is much less useful than high-affinity substituted benzamides which have been developed more recently. Kessler et al. [20] performed [¹⁸F]fallypride PET studies in six schizophrenic subjects treated with olanzapine and six treated with haloperidol to examine the occupancy of striatal and extrastriatal D₂/D₃ receptors. [¹⁸F]setoperone PET studies were performed in seven olanzapine-treated subjects to determine 5-HT_{2A} receptor occupancy. Occupancy of DA D₂ receptors by olanzapine was not significantly different from that seen with haloperidol in the putamen, ventral striatum, medial thalamus, amygdala, or temporal cortex, that is, 67.5–78.2% occupancy; no preferential occupancy of DA D₂ receptors was seen in the ventral striatum, medial thalamus, amygdala, or temporal cortex. There was significantly lower occupancy of substantia nigra (SN)/VTA D₂ receptors in olanzapine- than haloperidol-treated subjects, that is, 40.2 versus 59.3% ($p = 0.01$); in olanzapine-treated subjects, the SN/VTA DA D₂ receptor occupancy was significantly lower than that seen in the putamen, that is, 40.2 versus 69.2% ($p = 0.01$). Sparing of SN/VTA DA D₂ receptor occupancy was suggested to contribute to the low incidence of EPSs in the olanzapine-treated patients. Similar results have now been obtained with clozapine- and quetiapine-treated patients [21]. Clozapine, the most effective of these agents, was found to produce the lowest occupancy of SN/VTA D₂ receptors. It is not possible to resolve the SN and VTA binding. Thus, it could be that binding by the atypical APDs to either or both regions is reduced. In any case, it does not seem likely that this alone could account for all the differences between typical and atypical APDs. Grunder et al. [22] studied the occupancy of extrastriatal D₂/D₃ DA receptors by clozapine using [¹⁸F]fallypride in 15 patients with schizophrenia. Mean D₂/D₃ receptor occupancy was statistically significantly higher in cortical (inferior temporal cortex 55%) than in striatal regions (putamen 36%, caudate 43%, $p < 0.005$). Occupancy of cortical receptors approached 60% with plasma clozapine levels in the range of 350–400 ng/mL, which corresponds to the threshold for antipsychotic efficacy of clozapine. These authors concluded that extrastriatal D₂/D₃ receptor binding of clozapine may be more relevant to its antipsychotic actions than striatal binding.

It has been suggested that atypicality may be due to rapid dissociation from the DA D₂ receptor due to its relatively easy displacement by surges of endogenous DA [23, 24]. It has also been proposed that rapid and extensive displacement of clozapine and quetiapine from binding sites by endogenous DA accounts for the low occupancy of striatal D₂ receptors by these drugs [23]. However, it is not clear on what basis these agents achieve their antipsychotic action if they are equally easily displaced from limbic D₂ receptors. Moreover, numerous atypical APDs (e.g., sertindole, risperidone, asenapine, and ziprasidone) are comparable to haloperidol in their rate of dissociation from the D₂ receptor, based upon their equally high affinity for that receptor. Thus, this theory fails to account for the atypical profile of these high-D₂-affinity atypical APDs. However, relatively easy displacement from D₂ receptors of low-D₂-affinity atypical APDs such as clozapine and quetiapine could contribute to their very low risk of EPSs and greater tolerability in patients with Parkinson's disease. Seeman [25] has proposed the fast-off theory as the basis for the atypical features of amisulpride, but it is difficult to understand what distinguishes it from other D₂/D₃ antagonists which are not atypical. The fast-off theory has had no apparent impact on the process of antipsychotic drug discovery development and, thus, has not met that important clinical test. This is in marked contrast to the hypothesis, to be discussed, that atypicality is related to the combination of a partial decrease in dopaminergic function coupled to blockade of 5-HT_{2A} receptors or stimulation of 5-HT_{1A} receptors [26, 27].

12.3 D₁, D₃, AND D₄ RECEPTORS: SUBSTITUTED BENZAMIDES

The central nervous system (CNS) contains four subtypes of DA receptor other than the D₂ receptor, the D₁, D₃, D₄, and D₅ receptors. Whether these DA receptors play a role in the action of current antipsychotic drugs or are potential targets for future ones is poorly understood. Phenothiazine and thiothanthines, but not butyrophenones such as haloperidol or substituted benzamides such as amisulpride, are effective D₁ antagonists. Clozapine is a D₁ partial agonist [28] and has a greater extent of occupancy of D₁ receptors than any other antipsychotic drug [16]. There is some indirect evidence that the ability of the atypical APDs to improve cognition in schizophrenia may be mediated through effects on D₁ receptors via their role in long-term potentiation [29]. Specific D₁ receptor antagonists have been evaluated in the treatment of schizophrenia, but no clear evidence of beneficial therapeutic activity was obtained in pilot studies [30, 31].

The cloning of the D₄ receptor provoked much interest in the possibility that this was a key mechanism in the action of atypical APDs. This idea first originated from the observation that clozapine differed from other antipsychotics in having significantly higher affinity for the D₄ than for the D₂ receptor [32], a finding not supported by a number of other studies. Interest in the D₄ receptor as a target for antipsychotic drugs has waned after the completion of three negative randomized clinical trials with D₄ receptor antagonists fananserin [33], L-745,870 [34], and sonepiprazole [35].

Schwartz et al. [36] have suggested that the D₃ receptor, which is relatively highly expressed in limbic and cortical areas, may represent an important target for antipsychotic drugs which generally have similar affinities for D₂ and D₃ receptors. Clozapine has modest affinity for D₃ receptors although most of the other atypical

APDs related to clozapine do not. The discriminative stimulus for clozapine sometimes but not always generalizes to D_3 antagonists [37]. SB-277011-A has high affinity and selectivity for the D_3 receptor and good brain bioavailability [38]. This compound was active in preventing isolation-induced deficits in prepulse inhibition (PPI), a putative animal model for antipsychotic activity, but was not effective to block either amphetamine- or phencyclidine (PCP)-induced locomotor activity, which has much more validity in that regard [38]. However, subchronic administration of SB-277011-A selectively decreased the firing rate of VTA but not nigrostriatal DA neurons in the rat, indicating a clozapine-like profile [39]. In a microdialysis study in rats, the acute administration of SB-277011-A significantly increased extracellular levels of DA, norepinephrine (NE), and acetylcholine (ACh) without affecting levels of 5-HT in the anterior cingulate region of the medial PFC (mPFC). As will be discussed, this is similar to the profile we and others have reported with clozapine and other atypical APDs [40, 41]. Clinical trials of selective D_3 antagonists have not yet been reported.

The substituted benzamides are an interesting group of APDs and like the butyrophenones may include both typical and atypical APDs. The prototype is sulpiride, which is generally thought of as a typical APD, while the drug in widespread use in Europe but not the United States is amisulpride [42]. It has been suggested that the low EPS profile of sulpiride and amisulpride is due to selective antagonism of D_2/D_3 receptors in the mesocortico/limbic system [43]. Using single-proton emission computerized tomography (SPECT) with [^{123}I] epidepride as the ligand, eight amisulpride-treated patients (mean dose 406 mg/day) showed moderate levels of D_2/D_3 receptor occupancy in the striatum (56%) and significantly higher levels in the thalamus (78%) and temporal cortex (82% [44]). This finding suggests that modest striatal D_2 receptor occupancy and preferential occupancy of limbic cortical dopamine D_2/D_3 receptors may be major factors which explain the therapeutic efficacy and low-EPS profile of amisulpride. However, the risk of tardive dyskinesia with sulpiride is higher than that with other typical APDs [45]. On the other hand, the risk with amisulpride has been reported to be in the same range as other atypical APDs [46]. However, no differences in the mechanism of action of these two drugs have been reported as yet, suggesting there is some additional feature of the pharmacology of amisulpride that has yet to be identified. Another contrast is that sulpiride has been reported to impair cognitive functioning in normal volunteers [47] while amisulpride has been reported to improve some aspects of cognition in schizophrenia, but the data are very limited and did not involve a control group [48]. The clinical profile of amisulpride and its mechanism of action are worthy of more extensive investigation.

12.4 PARTIAL DOPAMINE AGONISTS

Most antipsychotic drugs which have affinity for D_2 and D_3 receptors are inverse agonists at both receptors [49]. However, some are partial D_2/D_3 agonists, for example, aripiprazole, bifeprunox [50], and *N*-desmethylozapine (NDMC), the major metabolite of clozapine [49, 51, 52]. Partial agonists, by definition, produce lesser activation of the D_2/D_3 receptors than the full agonist and as such will produce smaller functional responses than the endogenous neurotransmitter [53]. Partial

agonists are particularly more potent as agonists when there is high receptor reserve. Thus, DA partial agonists are more likely to stimulate DA autoreceptors than postsynaptic DA receptors. Because of this, they diminish dopaminergic stimulation through a dual mechanism: suppression of the release of DA by stimulating autoreceptors and blocking the response to the full agonist at postsynaptic receptors. There have been many attempts to develop DA autoreceptor agonists for the treatment of schizophrenia but all failed until recently, when DA partial agonists, which also had 5-HT_{2A} inverse agonist or 5-HT_{1A} partial agonist properties or both, were tested and were found to be effective and tolerable. Thus aripiprazole, an approved atypical antipsychotic drug [51], is a D₂ partial agonist and both a 5-HT_{2A} inverse agonist and 5-HT_{1A} partial agonist. Bifeprunox is a partial agonist at both the D₂ and 5-HT_{1A} receptors only, with no 5-HT_{2A} antagonist properties [50]. It is in phase III testing as an antipsychotic drug. Both drugs produce minimal EPSs at clinically effective doses. As agonists, both suppress serum prolactin levels. Aripiprazole, but not bifeprunox, has been reported to reverse deficits in social interaction in rats produced by the NMDA receptor antagonist PCP [52]. The contribution of 5-HT_{2A} inverse agonism or 5-HT_{1A} partial agonism to their efficacy will be discussed subsequently. Functional selectivity of some DA agonists, including partial agonists, for specific types of DA receptors (e.g., autoreceptors vs. postsynaptic D₂ receptors) [54, 55] has been demonstrated, that is, differential activation of different isoforms of a D₂ receptor, thus implying variable “intrinsic activity” of an agonist [56]. Whether aripiprazole or bifeprunox also demonstrate functional selectivity for D₂ or D₃ receptors and whether this contributes to their atypical antipsychotic properties remain to be seen. Li et al. [57] have reported that aripiprazole, at a dose of 0.3 mg/kg, which corresponds to clinically effective doses, can increase the release of DA in the rat mPFC and hippocampus. These results have been replicated [58]. It will be of interest to determine if there are any partial DA agonists, with no significant affinity for 5-HT_{2A} or 5-HT_{1A} receptor which are effective and tolerable APDs or whether some other potentiating mechanism (e.g., M₁ agonism, to be discussed) is needed.

12.5 ROLE OF 5-HT_{2A}, 5-HT_{2C}, 5-HT_{1A}, AND OTHER 5-HT RECEPTORS

Clozapine and a group of other atypical antipsychotic drugs have a greater affinity for 5-HT_{2A} than D₂ receptors [26, 59, 60]. The hypothesis that a relatively high affinity for the 5-HT_{2A} receptor compared to their affinities for the D₂ receptor was the basis for the difference between atypical and typical APDs contributed to the development of the newer antipsychotic agents listed above, all of which support the previously mentioned hypothesis of high affinity for 5-HT_{2A} and low affinity for D₂ receptors [59, 60]. However, other 5-HT receptors may be important in the action of clozapine and other recently introduced antipsychotic agents or of potential value for developing more effective or better tolerated antipsychotic agents. These include 5-HT_{1A}, 5-HT_{2A}, 5-HT_{2C}, 5-HT₃, 5-HT₆, and 5-HT₇ receptors [61]. While some of the atypical APDs developed on the basis of the 5-HT_{2A}/D₂ hypothesis also have affinities for 5-HT_{2C}, 5-HT₃, 5-HT₆ or 5-HT₇ receptors in the same range as that for the 5-HT_{2A} receptor, this is not characteristic of all of these agents and, thus, it is not likely that affinities for these receptors are primary factors contributing to the

low-EPS profile of the entire class of agents [60, 62, 63]. However, this does not rule out that actions at various 5-HT receptor contribute to low-EPS effects of specific drugs or other actions, for example, cognitive improvement or improvement in negative symptoms.

12.6 ATYPICAL ANTIPSYCHOTICS AND 5-HT_{2A} RECEPTOR

5-HT_{2A} receptors have been implicated in the genesis of as well as the treatment of psychosis, negative symptoms, mood disturbance, and EPSs. The hallucinogenic effect of indole hallucinogens has been related to stimulation of 5-HT_{2A} rather than 5-HT_{2C} receptors [64]. Numerous studies have examined the density of 5-HT_{2A} receptors in various cortical regions of patients with schizophrenia with decreased [65, 66], increased [67], or normal levels reported. It is well established that some typical and atypical APDs can decrease the density of 5-HT_{2A} receptors [68] so the postmortem results noted above may be related to drug treatment. A PET study in never-medicated patients with schizophrenia confirmed this decrease in cortical 5-HT_{2A} receptor density [69], but other studies which were not exclusively with never-medicated patients found no decrease in 5-HT_{2A} receptors in the cortex of patients with schizophrenia [70, 71]. Further study of this important issue is warranted. The antipsychotic effect of clozapine and other atypical ADPs has been attributed, in part, to its ability to block excessive 5-HT_{2A} receptor stimulation without excessive blockade of D₂ receptors [26]. This conclusion is consistent with the high occupancy of 5-HT_{2A} receptors produced by clozapine at clinically effective doses and its low occupancy of D₂ receptors (in the 30–50% range as measured with the [³H]raclopride), the latter being significantly below the 80–100% occupancy usually produced by typical neuroleptic drugs [16, 21, 72]. The occupancy of 5-HT_{2A} and D₂ receptors has been studied with other atypical APDs such as risperidone, olanzapine, sertindole, and quetiapine with results similar to those of clozapine; all are more potent 5-HT_{2A} inverse agonists and D₂ antagonists at appropriate doses, but less so than clozapine. Some of these agents (e.g., risperidone) produce high D₂ occupancy at moderately high doses [18, 72] but do not cause the level of EPSs associated with such high levels of occupancy when produced by typical APDs. The most likely reason for this difference is the blockade of 5-HT_{2A} receptors by the atypical APDs.

The bell-shaped dose–response curve of risperidone, with higher doses being less effective than lower doses [73], suggests that excessive D₂ receptor antagonism may diminish some of the beneficial effects of 5-HT_{2A} receptor blockade [63]. This is supported by two recent studies in which risperidone was added to clozapine treatment of partial responders in placebo-controlled randomized clinical trials. Placebo was generally superior to or equal to risperidone in a number of outcome measures [74, 75]. The highly selective 5-HT_{2A} inverse agonist M100907, formerly MDL 100907, has been found in a controlled study to have some efficacy for treating positive and negative symptoms in hospitalized schizophrenic patients [76]. However, because it was less effective than haloperidol, no further testing in schizophrenia followed. Nevertheless, the concept that 5-HT_{2A} receptor blockade may be useful to treat some forms of psychosis, especially when combined with weak D₂ receptor blockade, is deserving of further testing. The 5-HT_{2A/2C} selective antagonist SR46349B [77] was recently reported to be nearly as effective as haloperidol in

treating patients with schizophrenia in a double-blind clinical trial [78]. NRA0045, which has potent 5-HT_{2A}, D₄, and α_1 but negligible D₂ or D₃ receptor blockade, has been found to have atypical antipsychotic properties in rodents [79, 80]. The selective 5-HT_{2A/2C} inverse agonist ACP 103 [81, 82] is being tested as monotherapy in the treatment of 3,4-dihydroxy-L-phenylalanine (L-DOPA) psychosis and schizophrenia. Low doses of three atypical APDs, clozapine, quetiapine, and melperone [83], are effective and tolerable in the treatment of L-DOPA psychosis. We have proposed that this is due to their 5-HT_{2A} receptor blockade, sparing D₂ receptors [84]. The role of 5-HT_{2A} receptor blockade in the action of clozapine and possibly other drugs with potent 5-HT_{2A} affinities is supported by the evidence that the *His452Tyr* allele of the 5-HT_{2A} receptor, which is present in 10–12% of the population, is associated with a higher frequency of poor response to clozapine [85]. In addition, the T102C single-nucleotide polymorphism has been reported to be related to response to clozapine [86]. Taken together, the evidence from clinical trial data suggests that 5-HT_{2A} receptor blockade may contribute to antipsychotic drug action.

There is additional evidence consistent with the relevance of 5-HT_{2A} receptor blockade for APD action. Thus, M100907, or other selective 5-HT_{2A} receptor inverse agonist, either alone or in combination with selective antagonists of other receptors, has been found to be effective in various animal models of psychosis. These include (a) blockade of amphetamine-induced locomotor activity and inhibition of the firing of VTA dopaminergic neurons [87]; (b) blockade of PCP- and dizocilpin (MK-801)-induced locomotor activity [88, 89]; (c) blockade of MK-801-induced prepulse inhibition [90]; and (d) antipsychotic-like activity in the paw test [91], among others. Of particular interest is the report of Wadenberg et al. [92] that the combination of an ED 50 dose of raclopride, a D₂ receptor antagonist, and M100907, but not M100907 alone, was effective in blocking the conditioned avoidance response. They concluded that 5-HT_{2A} antagonism alone could not achieve an antipsychotic action but that minimal blockade of D₂ receptors was required to achieve such an effect. This corresponds much more closely to the apparent clinical situation than does the models above where M100907 alone was effective, for example, blockade of PCP- or MK-801-induced locomotor activity. ACP 103 is another selective 5-HT_{2A/2C} inverse agonist [93] which has been shown to potentiate the effect of haloperidol and risperidone to enhance cortical DA efflux in rats [94]. Gardell et al. [95] have recently reported that ACP 103 reduced the dose of haloperidol and risperidone required for activity in the amphetamine- or MK-801-induced hyperactivity models and suppressed haloperidol-induced hyperprolactinemia in mice.

Additional evidence for the greater importance of 5-HT_{2A} and D₂ receptor interactions in the regulation of mesocorticolimbic versus nigrostriatal DAergic activity comes from two studies of Olijslagers et al. [96, 97] using midbrain rat slices and electrophysiological recording of the activity of A9 and A10 DA neurons. They first reported that 5-HT (20 μ M) in combination with quinpirole (30 nM), a D₂ agonist, enhanced the reduction of the firing rate in both A9 and A10 DA neurons, compared to quinpirole (30 nM) alone. However, the 5-HT_{2A/2C} agonist 1-(2,5-dimethoxy-4-iodophenyl)-2-aminopropane (DOI, 500 nM) enhanced quinpirole-induced reduction of firing rate in the A10 but not A9 DA neurons. The selective 5-HT_{2A} receptor antagonist MDL100907 and the selective 5-HT_{2C} receptor antagonist SB242084 (50 and 500 nM) both abolished the enhancement of quinpirole-induced reduction by either 5-HT or DOI, suggesting the involvement of direct and

indirect (possibly via interneurons) modulation pathways in A10. 5-HT_{2A} receptors have been localized on the cell bodies of the A10 DA and other nondopaminergic VTA neurons [98].

Olanzapine and clozapine, two atypical APDs, more potently reversed the amphetamine-induced inhibition in A10 neurons compared to A9 neurons [96]. Olijslagers et al. [96] also reported that risperidone (0.03 and 0.1 μ M) reversed amphetamine-induced inhibition of firing activity similarly in A9 and A10. Risperidone has a higher affinity for D₂ relative to 5-HT_{2A} receptors than either clozapine or olanzapine. The dopamine D₂ receptor antagonist (–)sulpiride (0.05 and 1 μ M) reversed the amphetamine (10 μ M)–induced inhibition of firing activity in A9 and A10 neurons. However, the selective 5-HT_{2A} receptor antagonist M100907 (0.05 μ M), strongly enhanced the reversal of amphetamine-induced inhibition by (–)sulpiride in A10, but its effectiveness to enhance the effect of sulpiride was much less in A9 DA neurons. They suggested that 5-HT_{2A} in combination with DA D₂ receptor antagonism may play a role in atypical APD differential effects on nigrostriatal and mesocorticolimbic DAergic activity, leading to some of the clinical differences between typical and atypical APDs.

The 5-HT_{2A} and 5-HT_{1A} agonist psilocybin has been reported to impair cognitive function in normal volunteers [99]. Increased dopaminergic activity in the NAC and other mesolimbic and possibly cortical regions may contribute to positive symptoms, including formal thought disorder. The 5-HT_{2A/2C} agonist DOI, which is hallucinogenic in humans, itself had no effect on basal DA release, potentiated amphetamine-induced DA release, and attenuated the ability of apomorphine, a direct-acting D_{1/2/3} agonist, to decrease DA release in the striatum [100]. There is now considerable evidence from both behavioral and neurochemical studies involving *N*-methyl-D-aspartate (NMDA) antagonists such as PCP and MK-801 that 5-HT_{2A} receptors modulate activate but not basal mesolimbic DAergic function [88, 101, 102]. Thus, stimulated DA release (e.g., with stress) may be increased in the forebrain terminal regions secondary to enhanced stimulation of 5-HT_{2A} receptors. Agents which block the effect of excessive but not basal 5-HT_{2A} receptor stimulation may be the most useful clinically. M100907 has been found to diminish the increase in DA efflux in the NAC produced by haloperidol [103] or *S*-sulpiride [27]. M100907 infused directly into the mPFCs resulted in a concentration-dependent blockade of K(+)–stimulated DA release and also blocked increases in DA release produced by the systemic administration of DOI. Thus, local 5-HT_{2A} antagonism has an inhibitory effect on stimulated DA release and suggest that cortical 5-HT_{2A} receptors potentiate the phasic release of mesocortical DA [104]. The local (in the mPFC) and systemic administration of DOI increased the firing rate and burst firing of DA neurons and DA release in the VTA and mPFC [105]. The increase in VTA DA release was mimicked by the electrical stimulation of the mPFC. The effects of DOI were reversed by M100907. These results indicate that the activity of VTA DA neurons is under the excitatory control of mPFC 5-HT_{2A} receptors. Taken together, these data suggest that blockade of cortical 5-HT_{2A} receptors, by itself, may have antipsychotic action when dopaminergic activity is slightly to moderately increased. More studies are needed to define the ability of 5-HT_{2A} receptor antagonists to potentiate the action of low doses of D₂ receptor blockers in animal models as well as the clinic. Jakab and Goldman-Rakic [106] have demonstrated that 5-HT_{2A} receptors are located on most cortical pyramidal neurons, especially those above and below layer

IV, as well as on many (γ -aminobutyric acid) (GABA)–ergic interneurons known to specialize in the perisomatic inhibition of pyramidal cells: large- and medium-size parvalbumin- and calbindin-containing interneurons. Together they may play a crucial role in psychosis by virtue of their ability to modulate intracortical and cortical–subcortical glutamatergic neurotransmission. This could contribute to the ability of 5-HT_{2A} inverse agonists, including those atypical APDs which are potent in this regard, to attenuate some of the behavioral effects of PCP and ketamine.

12.7 5-HT_{2A} RECEPTOR BLOCKADE, ENHANCEMENT OF CORTICAL DA EFFLUX, AND COGNITIVE FUNCTION IN SCHIZOPHRENIA

As previously mentioned, clozapine and related atypical APDs (e.g., risperidone and olanzapine) have been shown to modestly improve selected areas of cognitive function in most patients with schizophrenia [9]. The effect of these agents on cognition may be dependent, in part, upon their ability to increase the release of DA in PFC and hippocampus, which depends, in part, on their serotonergic actions [107, 107a]. We have found that the combination of a saturating dose of a 5-HT_{2A} inverse agonist/antagonist and a dose of D₂ antagonist which only partially blocks D₂ receptors leads to increased DA release in the frontal cortex [94, 108, 109]. The 5-HT_{2A} receptor blockers do not potentiate D₂ receptor blockade when the dose of the latter is saturating [108]. This is consistent with the hypothesis that at clinical doses atypical APDs achieve partial blockade of D₂ receptors relative to 5-HT_{2A} receptor blockade. In addition, the atypical APDs enhance efflux of ACh in the PFC and hippocampus of rodents [110–113]. It is possible that this effect may also contribute to their ability to improve cognition.

5-HT_{2C}, 5-HT₃, 5-HT_{1A}, and 5-HT₄ receptors have also been reported to have significant effects on ACh release in the rat PFC [114–118]. Impairment of working memory in humans following administration of the 5-HT_{1A} agonist flesinoxan has been reported [119]. Sumiyoshi et al. [120], on the other hand, have found that tandospirone, a 5-HT_{1A} partial agonist, can improve other domains of cognition in patients with schizophrenia treated with typical neuroleptic drugs.

Brain-derived neurotrophic factor (BDNF) regulates survival, differentiation, synaptic strength, and neuronal morphology in the cerebral cortex and hippocampus in frontal and other cortical areas while decreasing its expression in the dentate gyrus granule cell layer. The BDNF gene *Val66Met* polymorphism has been reported to be associated with schizophrenia and response to clozapine [121]. It has recently been demonstrated that stimulation of 5-HT_{2A} receptors by the 5-HT_{2A/2C} agonist DOI and stress increases the expression of BDNF in cortex and hippocampus [122]. These effects were blocked by the 5-HT_{2A} antagonist M100907 and ritanserin, respectively, which by themselves did not have any effect in these regions. Electrophysiological studies with slices from rats following chronic treatment with clozapine or haloperidol showed that chronic clozapine but not haloperidol treatment resulted in an attenuation of the effect of the activation of 5-HT_{2A} receptors without changing response to 5-HT_{1A} and 5-HT₄ receptor activation. These data are consistent with the hypothesis that chronic clozapine selectively attenuates 5-HT-mediated excitation in neuronal circuitry of the frontal cortex while leaving 5-HT-mediated inhibition intact [123]. Clozapine and olanzapine upregulated BDNF messenger RNA (mRNA)

expression in CA1, CA3, and dentate gyrus regions of the rat hippocampus whereas haloperidol (1 mg/kg) downregulated BDNF mRNA expression in both CA1 ($p < 0.05$) and dentate gyrus ($p < 0.01$) regions [124]. Neither acute nor chronic clozapine treatment significantly affected the expression of BDNF mRNA in various brain areas. However, the NMDA antagonist MK-801 (5 mg/kg; 4 h) significantly increased BDNF mRNA in the entorhinal cortex, an effect which was attenuated by pre-treatment with clozapine and haloperidol [125]. These data suggest that clozapine-like atypical APDs, via their 5-HT_{2A} antagonism, might modulate the activity of BDNF and possibly other growth factors.

Transcription factors of the Nur family (Nurr1, Nur77, and Nor-1) are orphan nuclear receptors that have been associated with DA neurotransmission. Nurr1 is involved in midbrain DA neuron development. Nur77 and Nor-1 are expressed in dopaminergic areas such as the striatum, NAC, and PFC. Modulation of Nur77 and Nor-1 mRNA expression by antipsychotics can be used to calculate an index that is predictive of the typical or atypical profile of antipsychotic drugs [126]. Inductions of Nur by antipsychotic drugs was correlated with DA D₂ receptor in the striatum and NAC. The 5-HT_{2A}/D₂ affinity ratio of antipsychotics also predicted these patterns of inductions. These data suggest that typical and atypical APDs might induce distinct Nur-dependent transcriptional activities, which may contribute to their pharmacological effects.

12.8 5-HT_{2A} RECEPTOR BLOCKADE AND EXTRAPYRAMIDAL FUNCTION

Several lines of evidence suggest that potent 5-HT_{2A} receptor blockade is relevant to the low-EPS profile of clozapine but that 5-HT_{2A} receptor blockade by itself cannot explain the low-EPS liability of these agents. In order to test the role of 5-HT_{2A} receptor blockade, Meltzer et al. [26] studied a group of compounds which had antipsychotic activity in human or animal models that are thought to be predictive of antipsychotic activity and which produced less EPSs in humans or weak catalepsy in animals. The ratio of affinity for 5-HT_{2A} to D₂ receptors was the best predictor of atypicality [26]. This continues to be supported by further research [11]. Ishikane et al. [127] reported that M100907 is able to block haloperidol-induced catalepsy only at low doses of haloperidol. Weiner et al. [128] profiled antipsychotic drugs for functional activity at 33 of the 36 known human monoaminergic G-protein-coupled receptors using the mammalian cell-based functional assay Receptor Selection and Amplification Technology (R-SAT). Competitive antagonism of D₂ receptors and inverse agonism of 5-HT_{2A} receptors were nearly uniform throughout this class, with typical agents demonstrating low 5-HT_{2A}/D₂ ratios and atypical agents demonstrating high ratios.

12.9 ROLE OF 5-HT_{2C} RECEPTOR IN ANTIPSYCHOTIC DRUG ACTION: 5-HT_{2A} AND 5-HT_{2C} INTERACTIONS

There has been extensive consideration given to the role of 5-HT_{2C} receptors in the action of atypical APDs. The 5-HT_{2C} receptor is found throughout the CNS,

including the VTA and the NAC [129]. The 5-HT_{2C} receptor is constitutively active, meaning it is activated even in the absence of agonist [130, 131]. The *Ser23Cys* single-nucleotide polymorphism of the *HTR2C* receptor gene has been reported to be predictive of response to clozapine [132]. The *HTR2C* receptor gene undergoes extensive RNA editing in the brain, which leaves open the possibility that there are multiple forms of the receptor in brain [133]. This in turn suggests the *HTR2C* gene may be very important to epigenetic events which may influence the course of schizophrenia and response to treatment [134, 135]. Because of the development of specific 5-HT_{2C} agonists, inverse agonists, and antagonists, it has been possible to obtain evidence for a tonic inhibitory action of 5-HT_{2C} receptors on the burst firing of mesolimbic and mesocortical dopaminergic neurons. Thus, the firing rate of VTA DA neurons is inhibited or increased by 5-HT_{2C} agonists or antagonists, respectively. This is consistent with microdialysis studies which show that 5-HT_{2C} antagonists increase extracellular concentrations of DA in the NAC and mPFC [101, 136, 137]. These studies establish that the 5-HT_{2C} receptor is most important for regulation of tonic DA release. We have recently reported that the combination of the 5-HT_{2C} neutral antagonist SB242984 1.0 mg/kg and low- or high-dose haloperidol enhanced the release of cortical and NAC DA in rats using microdialysis [82]. SB242084 0.2 mg/kg produced significant increase in DA efflux in the NAC, not the mPFC. The extent of both 5-HT_{2C} and 5-HT_{2A} receptor blockade, in relation to D2 receptor blockade, may be a key factor in the relative ability of atypical APDs to preferentially increase cortical DA efflux compared to NAC DA efflux [82].

Early studies found no significant differences between groups of atypical APDs, and typical neuroleptics with regard to the affinity for 5-HT_{2C} receptor or the difference between 5-HT_{2C} and D₂ affinities have been reported [60, 62, 138]. A large group of atypical antipsychotic drugs (sertindole, clozapine, olanzapine, ziprasidone, risperidone, zotepine, tiospirone, fluperlapine, tenilapine) displayed potent inverse agonist activity at rat and human 5-HT_{2C} receptors [139]. Typical antipsychotic drugs of various chemical classes did not. Several typical antipsychotic drugs (chlorpromazine, thioridazine, spiperone, thiothixene) displayed neutral antagonist activity by reversing clozapine inverse agonism. These data are consistent with the concept that 5-HT_{2C} receptor blockade of constitutive and stimulated 5-HT_{2C} receptor stimulation may play a role in the action of atypical APDs and be involved in the etiology of schizophrenia and other forms of psychosis. Chronic sertindole but not clozapine downregulated cortical 5-HT_{2C} receptors [140]. 5-HT_{2C} receptor antagonism appears to have useful effects on certain types of memory impairment. Thus, SB-200646 antagonized memory impairment due to some 5-HT_{2A/AC} agonists and dizocilpine but not scopolamine [141]. Of the approved atypical APDs, some have equivalent affinities for the 5-HT_{2A} and 5-HT_{2C} receptors (clozapine, olanzapine, sertindole) while others are more selective for the 5-HT_{2A} receptor (risperidone, quetiapine, ziprasidone). This difference roughly corresponds with potential to produce weight gain in that clozapine and olanzapine cause the greatest weight gain, quetiapine intermediate, and aripiprazole, bifeprunox, risperidone, and ziprasidone the least. The 759T polymorphism in the promoter region of the 5-HT_{2C} receptor gene has been found to be associated with clozapine-induced weight gain, response to clozapine, and tardive dyskinesia [134].

An interesting aspect of the 5-HT_{2C} receptor with regard to antipsychotic action is that 5-HT_{2C} antagonism may be functionally opposed to 5-HT_{2A} antagonism.

Meltzer et al. [142] reported that atypical APDs were more likely to be weak 5-HT_{2C} and potent 5-HT_{2A} antagonists compared to typical neuroleptic drugs. There is some evidence for a functional antagonism of these two receptors which may be expressed on the same neurons. Thus, Martin et al. [89] found that ritanserin, a mixed 5-HT_{2A/2C} antagonist, blocked the ability of M100907 to antagonize the effect of MK-801 to increase locomotor activity in mice.

12.10 ROLE OF 5-HT_{1A} RECEPTOR IN ANTIPSYCHOTIC DRUG ACTION: 5-HT_{1A} AND 5-HT_{2A} INTERACTIONS

5-HT_{1A} receptors are located pre- and postsynaptically. The presynaptic 5-HT_{1A} receptor is an autoreceptor located on cell bodies of raphe neurons; stimulation leads to inhibition of firing of 5-HT neurons. Stimulation of postsynaptic 5-HT_{1A} receptors leads to hyperpolarization of pyramidal neurons, opposite to the effect of stimulation of 5-HT_{2A} receptors. Approximately 60% of rat PFC glutamatergic cells were found to have 5-HT_{1A} mRNA, as did approximately 25% of generalized anxiety disorder (GAD)-expressing cells [143]. 5-HT_{1A} receptor agonists have effects similar to 5-HT_{2A} receptor inverse agonists in a variety of functions [144, 145]. A few examples will be given. For example, DOI injected bilaterally into the rat mPFC elicited a dose-dependent head-twitch response. This effect is inhibited by the 5-HT_{1A} agonist 8-OH-DPAT as well as the 5-HT_{2A} inverse agonists M100907 and ketanserin. Ahlenius [146] first suggested that stimulation of 5-HT_{1A} receptors might produce an antipsychotic-like action on the basis of behavioral studies in animals using the direct 5-HT_{1A} agonist 8-OH-DPAT. Subsequent studies demonstrated that 8-OH-DPAT enhanced the antipsychotic-like effect of the D₂/D₃ antagonist raclopride [147] and of haloperidol [148] and antagonized the catalepsy induced by the D₁ agonist SCH23390 in rats [149]. The beneficial effect of 5-HT_{1A} agonists appears to be mediated by inhibition of median raphe serotonergic neurons [150]. Ichikawa and Meltzer [151] demonstrated that 8-OH-DPAT inhibited the ability of clozapine and low-dose risperidone, but not haloperidol, to increase extracellular DA levels in the NAC and the striatum of conscious rats. The effect in the NAC would be expected to enhance the antipsychotic effect of these agents by reducing dopaminergic activity in this region which is believed to participate in the generation of psychotic symptoms. Several atypical APDs are partial agonist at the 5-HT_{1A} receptor, including aripiprazole, bifeprunox, clozapine, ziprasidone, quetiapine, and tiospirone. Their affinities for the 5-HT_{1A} receptor were similar to their affinities at the human D₂ receptor [152]. The ability of atypical APDs to increase DA efflux in the rat PFC and hippocampus is blocked, in part, by WAY-100635, a 5-HT_{1A} antagonist [27, 113, 153, 154]. This effect of 5-HT_{1A} receptors appears to be mediated by 5-HT_{1A} receptors in the PFC as it is blocked by local injection of a 5-HT_{1A} antagonist in the mPFC or by transection of cortical connections to the VTA [155]. These findings suggest that the combination of D₂ antagonism and 5-HT_{1A} agonism should produce an atypical antipsychotic agent [155a]. S16924 is an example of such a compound, and it has atypical properties very similar to those of clozapine in a variety of animal models [137]. The 5-HT_{1A} partial agonist S15535 enhanced the release of ACh in rat mPFC [156]. However, there is little evidence so far that the increase in ACh efflux in mPFC or hippocampus produced by atypical antipsychotic drugs is related to their

direct or indirect 5-HT_{1A} agonism [111, 113]. Bruins et al. [52] have suggested that the balance of activity at D₂ and 5-HT_{1A} receptors is important for the ability of antipsychotic drugs to reverse the deficit in social interaction, a putative model of negative symptoms, in rats.

12.11 ROLE OF 5-HT₆ RECEPTOR

Recent interest in the 5-HT₆ receptor in relation to the action of APDs has been based, in part, on the finding that some APDs, including the atypical APDs clozapine, olanzapine, and sertindole, as well as some antidepressant agents (e.g., clomipramine and amitriptyline), are relatively potent 5-HT₆ receptor antagonists [62, 157–160]. Regional analysis of receptor binding and the expression of 5-HT₆ receptor mRNA revealed the highest levels are found in the striatum, olfactory tubercle, NAC, cerebral cortex, and subfields of the hippocampus [157, 161–164]. Together, these data on expression and localization suggest possible involvement of 5-HT₆ receptors in cognitive, affective, and motor function.

It has been reported that clozapine, the prototypical antipsychotic drug, but not haloperidol, significantly decreased 5-HT₆ receptor expression in all subfields of the hippocampus [165]. As clozapine has a greater effect than haloperidol to improve some aspects of cognition in schizophrenia, it was suggested that downregulation of this receptor in the hippocampus might contribute to the ability of clozapine to enhance cognition [165]. This hypothesis is supported by a series of behavioral studies which demonstrate that the 5-HT₆ receptors may be involved in learning and memory [166–173]. These data suggest that 5-HT₆ receptor stimulation may interfere with learning and long-term memory function and the potential role for 5-HT₆ receptor antagonists for the enhancement of cognition in patients with schizophrenia. The high affinity of some atypical antipsychotic drugs for 5-HT₆ receptors and the localization of 5-HT₆ receptor in limbic and cortical regions of the brain suggest that 5-HT₆ receptors also play a role in the mechanism of action and pathophysiology of some aspects of schizophrenia. Minabe et al. [174] reported that high but not low doses of the selective 5-HT₆ receptor antagonist SB-271046 given acutely suppressed the firing rate of VTA DA neurons. Chronic administration altered the pattern of firing of these neurons, which are highly relevant to schizophrenia in a manner which differed from that of either typical or atypical APDs. It was suggested that clinical study of this type of agent would be of interest to determine its role, if any, in the treatment of schizophrenia. There has been only limited study of the role of the 5-HT₆ receptors in the modulation of DA or ACh release, which might be relevant to their ability to improve cognition, and the results have been inconsistent. 5-HT₆ receptor antagonists have been reported to increase extracellular ACh efflux in the cortex or hippocampus in two studies [175, 176]. However, another 5-HT₆ receptor antagonist RO 04-6790 failed to do so [112].

The 5-HT₆ receptor antagonist SB-271046, which has been shown to be effective in enhancing cognitive function in models of learning and memory [167, 169], had no effect on DA efflux in either the frontal cortex or dorsal hippocampus [177]. However, a recent study reported that SB-271046 produced a significant increase in DA release in the rat mPFC [178]. Pouzet et al. [179] found that SB-271046 dose dependently inhibited *d*-amphetamine-induced suppression of prepulse inhibition

(PPI), consistent with an antipsychotic action. However, Leng et al. [180] found no effect of two other 5-HT₆ antagonists in latent inhibition (LI) or PPI models in which clozapine was active. The 5-HT₆ receptor antagonist *N*-[4-methoxy-3-(4-methyl-1-piperazinyl)-phenyl]-5-chloro-3-methylbenzo-thiophene-2-yl sulfonamide monohydrochloride (SB-258510A) has been reported to produce greater potentiation of amphetamine-induced increase in extracellular DA release in the mPFC than the NAC [181]. Another 5-HT₆ receptor antagonist, SB-271046, potentiated amphetamine-induced DA release in the striatum [182]. Li et al. (in preparation) found that SB-399885, 3 and 10 mg/kg, a selective 5-HT₆ receptor antagonist, had no effect on cortical DA efflux but slightly increased hippocampal DA efflux in freely moving rats. However, SB-399885, 3 mg/kg, significantly potentiated the ability of haloperidol, a D₂ receptor antagonist, at a dose of 0.1 mg/kg, to increase DA release in the hippocampus but not the mPFC. SB-399885 also potentiated risperidone-, 1.0 mg/kg, induced DA efflux in both hippocampus and mPFC. These results suggest that the combined blockade of 5-HT₆ and D₂ receptor may contribute to the potentiation of haloperidol- or risperidone-induced DA efflux in the mPFC and hippocampus. In addition, other microdialysis studies suggest that the 5-HT₆ receptor may interact with DA mechanisms in the rat mPFC as antisense oligonucleotides partially antagonized the fluoxetine-induced cortical DA release [183]. Taken together these data suggest that 5-HT₆ receptors may have modulatory influence on DA efflux in the mPFC and hippocampus and, hence, may contribute to some of the clinical benefits of atypical APDs. 5-HT₆ receptor antagonists may also be useful as augmenting agents to improve cognitive dysfunction in schizophrenia. There is, however, insufficient evidence to conclude that they will be first-line treatments for the psychosis of schizophrenia.

12.12 ROLE OF SEROTONIN RELEASE IN ANTIPSYCHOTIC DRUG ACTION

The antagonism of multiple 5-HT receptors by clozapine would be expected to enhance the release of 5-HT by feedback mechanisms. Ichikawa et al. [184] reported that clozapine (20 mg/kg) and risperidone (1 mg/kg) but not olanzapine significantly increased extracellular 5-HT levels in the NAC and mPFC, respectively, whereas amperozide (1 and 10 mg/kg) increased extracellular 5-HT levels in both regions. Hertel et al. [185] reported similar results with risperidone and suggested that this might be relevant to its ability to improve negative symptoms. The enhancement of 5-HT efflux in the PFC may contribute to the ability of these agents to improve mood disorders and cognition [184]. Bortolozzi et al. [186] reported that clozapine blocked the efflux of cortical 5-HT produced by the hallucinogen DOI in rat brain by both 5-HT_{2A}- and α_1 -adrenoceptor-dependent mechanisms.

12.13 α_2 - AND α_1 -ADRENERGIC MECHANISMS AND ATYPICAL APDS

Many, but not all, of the atypical APDs which are multireceptor antagonists are also potent antagonists of α_1 or α_2 adrenoceptors or both. Thus, risperidone 9-hydroxyrisperidone, clozapine, olanzapine, zotepine, quetiapine, ORG-5222 (asenapine),

sertindole, and ziprasidone are potent α_1 antagonists [60]. Svensson [187] has suggested that blockade of α_1 adrenoceptors by APDs may contribute to suppression of positive symptoms whereas α_2 adrenoceptor blockade may be involved in relief of negative and cognitive symptoms. He postulates that α_1 adrenoceptor blockade may act by suppressing, at the presynaptic level, striatal hyperdopaminergia, and α_2 adrenoceptor blockade may act by augmenting and improving prefrontal dopaminergic functioning. Prazosin, an α_1 adrenoceptor antagonist, can, in the presence of weak D_2 receptor blockade, block the conditioned avoidance response [188] and has, similar to clozapine and other atypical APDs, been shown to increase DA efflux in the shell but not the core of the NAC, signifying a limbic rather than a striatal effect of α_1 antagonism [189]. These authors also suggested that α_1 antagonism may explain the atypical properties of sertindole which has as high an occupancy of D_2 receptors as typical APDs [190]. All of the atypical agents mentioned above are also potent α_2 antagonists with the exception of zotepine and sertindole. Kalkman et al. [191] have raised the possibility that the α_{2C} subtype may be particularly relevant to the anticataleptic actions of clozapine and iloperidone. However, McAllister and Rey [192] were unable to reverse the effects of loxapine or haloperidol on catalepsy with α_2 antagonists and showed that the effect of clozapine to reverse loxapine-induced increase in catalepsy was due to its anticholinergic rather than its adrenoceptor blocking properties.

The addition of idazoxan, an α_2 antagonist, to fluphenazine, a typical neuroleptic, was reported by Litman et al. [193] to have efficacy comparable to clozapine in a small group of neuroleptic-resistant patients with SCH. These results need to be replicated. Polymorphisms of the α_1 and α_2 receptors have been reported not to predict response to clozapine [194]. In this regard, it is of interest that idazoxan has been shown to preferentially increase DA efflux in the rat mPFC by an action at the terminal area [195]. This effect appears to be independent of dopaminergic activity. Subsequently, it was reported that the combination of raclopride, a D_2 antagonist, and idazoxan [196] produced a dose-dependent increase in NE in the mPFC of rats, as does systemic administration of clozapine, risperidone, ziprasidone, and olanzapine but also haloperidol [197]. This effect was closely coupled to the increase in DA efflux. Stimulation of α_2 receptors in cortex has been postulated to improve some types of cognitive function, for example, executive functions [198, 199]. Atypical antipsychotic drugs block α_2 receptors as noted above and would be expected to compromise cognitive function on this basis. However, these drugs also enhance the release of NE along with DA, which could overcome the effects of α_2 blockade. In fact, the atypical antipsychotic drugs have their least beneficial effect on executive function [9].

12.14 GLUTAMATERGIC MECHANISMS

Glutamate is the predominant excitatory neurotransmitter in the mammalian CNS. There are two types of glutamate receptors (GluRs): ionotropic GluRs, which are postsynaptic, multimeric ligand-gated ion channels classified into three groups related to group-selective agonists—NMDA, amino-3-hydroxy-5-methyl-isoxazole-4-propionic acid (AMPA) and kainite receptors—and metabotropic GluRs (mGluRs), which are members of family C of the G-protein-coupled receptors. None of the

currently available APDs have a high affinity for any of the ionotropic or metabotropic GluRs. Because of some similarities between the behavioral effects of NMDA receptor antagonists PCP and ketamine to the cognitive, negative, and positive symptoms of schizophrenia, it has been suggested that hypoglutamatergic function might contribute to schizophrenia [15, 200]. Laruelle et al. [201] summarized data for dopaminergic–glutamatergic interactions and proposed that hypoglutamatergic cortical function might lead to increased mesolimbic dopaminergic stimulation while diminution of mesolimbic dopamine function might reverse hypoglutamatergia. There have been numerous *in vivo* microdialysis studies of the effect of haloperidol and clozapine, as well as other antipsychotic drugs, to modulate the efflux of glutamate in cortex or striatum. The results are very mixed, reflecting differences in dosages, duration of treatment, use of anesthesia, and difficulty in separating glutamate efflux that is neuronally based from that due to the amino acid compartment [202]. Chronic treatment with haloperidol for six weeks followed by its withdrawal for four days elevated the basal, but not the veratridine-stimulated, extracellular levels of glutamate and aspartate [203] and enhanced the activity of cortical neurons. In contrast, six-week treatment with clozapine lowered both the basal and the stimulated levels of glutamate and aspartate but had no effect on the activity of cortical neurons. In a study of the effect of these two antipsychotic drugs on glutamate release from nerve terminals isolated from rat PFC, Yang and Wang [204] found that both haloperidol and clozapine inhibited glutamate release by ion-channel activities which influence nerve terminal excitability. At the present time, this effect of antipsychotic drugs on glutamate release cannot be related to their actions with any degree of confidence.

However, behavioral studies involving two models of cognitive impairment in schizophrenia, PPI and LI, provide more robust evidence that glutamatergic mechanisms may be important to the action of antipsychotic drugs. PPI of the startle response provides a measure of the ability of the organism to attenuate its response to repeated sensory input. The diminished response to sound- or air pulse-induced startle is usually used to test this reflex. Latent inhibition is a measure of the capacity to ignore irrelevant (nonreinforced) stimuli. Both PPI and LI are disrupted in schizophrenia. Treatment with NMDA receptor antagonists such as MK-801 or PCP can disrupt PPI and LI. Atypical antipsychotic drugs such as clozapine are more effective than typical antipsychotic drugs to reverse PPI [205, 206] or LI [207]. A recent study found no difference between typical and atypical APDs in reducing startle magnitude and increasing PPI in a mouse line which expresses low levels of the NMDA R1 subunit of the NMDA receptor [208]. The ability of drugs to reverse PCP-induced PPI disruption is correlated to their affinity for 5-HT_{2A}, not D₂ receptors [209]. Interestingly, the 5-HT_{2A} antagonist M100907 and the α_1 -adrenergic antagonist prazosin are also effective to reverse PPI deficits induced by NMDA receptor antagonists [205] but the α_2 antagonist RX821002, the M₁/M₄ muscarinic antagonist pirenzepine, or the GABA-A antagonist picrotoxin had no effect on basal or PCP-impaired PPI in mice [210]. As previously mentioned, 5-HT_{2A} receptors on cortical glutamatergic pyramidal neurons and GABAergic interneurons may have a key role in modulating glutamatergic function [143]. It has been suggested that the hallucinogenic action of 5-HT_{2A} agonists such as DOI is mediated by mGluR2/3-induced glutamate release as the head shakes induced by DOI are blocked by the mGluR2/3 agonist LY354740 and potentiated by the mGluR2/3 antagonist

LY341495 [211]. The combination of raclopride, a D_2 antagonist, and idazoxan, an α_2 antagonist, also was ineffective to block PCP-induced disruption of PPI [212]. Neonatal ventral hippocampal (NVH) lesions in rats induce behavioral abnormalities in adult rats that have some correspondence to cognitive deficits and negative symptoms in patients with schizophrenia, including deficits in PPI. Clozapine, olanzapine, and risperidone, but not haloperidol, reversed the deficit in PPI produced by an NVH lesion, possibly by enhancing glutamatergic function [213].

There is some evidence for a possible role of mGluR5 in schizophrenia [214]. mGluR2 agonists [215, 216] and positive allosteric modulators of the mGluR5 [217] have been shown to have activity in various animal models of antipsychotic activity, but there is no direct evidence that the current generation of atypical antipsychotic drugs act through either mechanism. Thus, neither clozapine nor raclopride were able to attenuate the PPI deficit in mGluR5 knockout mice [214].

12.15 CHOLINERGIC MECHANISMS

The concept of muscarinic agonism as a first-line treatment for schizophrenia was initiated by studies with xanomeline, which is a M_1/M_4 agonist or partial agonist. It was found to have some antipsychotic effects in patients with Alzheimer's disease or schizophrenia [218]. Preclinical studies with xanomeline and a closely related compound sabcomeline indicated it had the profile of an atypical APD, blocking conditioned avoidance response and producing minimal EPSs [219, 220]. Sabcomeline and possibly xanomeline also have indirect effects on D_2 receptor binding in the mouse striatum, as revealed by changes in the availability of D_2 receptors [221]. NDMC, the major metabolite of clozapine, has been reported to be an effective M_1 agonist in vitro [median effective concentration (EC_{50}) of 100 nM with 80% efficacy (relative to carbachol)] as well as in vivo [222, 223]. The M_1 agonist activity of NDMC is blocked by anticholinergic drugs and clozapine [222, 223]. These results confirm that NDMC is a potent, efficacious, M_1 receptor agonist, distinguishing it from the M_1 receptor antagonist properties of clozapine. No other antipsychotic has potent M_1 agonist properties [223, 224]. Clozapine is, in fact, a very weak partial agonist at M_1 receptors, a more efficacious agonist at M_2 and M_4 receptors, and to lack agonist activity at M_3 and M_5 receptors. NDMC also displayed high-potency interactions with all five human muscarinic receptors, but with increased agonist efficacy at M_1 , M_4 , and M_5 receptors when compared to clozapine. In contrast, olanzapine and *N*-desmethyloanzapine, both structurally related to clozapine and NDMC, lack agonist activity at human muscarinic receptors [223].

Li et al. [236] have reported that NDMC enhances DA and ACh efflux in the mPFC and hippocampus. Clozapine blocks the effects of NDMC on cortical and hippocampal ACh efflux and on hippocampal DA efflux [82]. The M_1 antagonist telenzepine also blocked the effect of NDMC on DA and ACh efflux. These results suggest that clozapine, acting through its predominant metabolite NDMC, may function as a direct-acting muscarinic receptor agonist in vivo. During pharmacotherapy with clozapine, the agonist actions of NDMC would be attenuated by the antagonistic actions of the parent compound. Thus, high NDMC levels, and particularly high NDMC/clozapine ratios, would increase agonist efficacy at muscarinic receptors, as predicted by mass action and by agonist/antagonist mixing

studies [225]. Clinical data support this notion. Not only does clozapine therapy usually lack the traditional anti cholinergic side effects of dry mouth, blurred vision, and urinary retention common to classical muscarinic antagonists, but also it is unique in its ability to frequently produce sialorrhea, an effect that can be blocked by the muscarinic antagonist pirenzepine [226]. Thus, the muscarinic receptor agonist activity of NDMC likely mediates this peripheral effect. The muscarinic agonist properties of NDMC may underlie some of the unique central effects of treatment with clozapine. If this hypothesis is correct, NDMC/clozapine ratios should be a better predictor of therapeutic response to clozapine, particularly for cognition, than absolute clozapine levels. As predicted, higher NDMC/clozapine ratios predicted improvement in multiple measures of cognition as well as negative symptoms [223]. Some other recent reports [227, 228] all suggest that the NDMC/clozapine ratio is a better predictor of clinical response to clozapine than clozapine levels alone and support the hypothesis that NDMC is a critical mediator of clozapine action.

12.16 NEUROKININ 3 RECEPTORS

The possible involvement of neurokinin 3 (NK₃) receptors in antipsychotic drug action has been recently reviewed [229]. The NK₃ antagonists osanetant and talnetant have been tested in schizophrenia. Osanetant showed some efficacy to treat positive symptoms with no evidence of EPSs in randomized, placebo- and haloperidol-controlled trials, indicating it met the criteria for an atypical APD [78]. Talnetant is in phase 2 testing but no results have been reported as of yet. Should either or both of these two agents prove clinically effective as monotherapy or as add-on therapy, it would be a major advance in the treatment of schizophrenia. Preclinical data suggest that NK₃ receptor antagonism achieves its antipsychotic efficacy by inhibition of dopaminergic activity via an indirect mechanism [230].

12.17 NEUROGENESIS

The evidence for the loss of neurons and decreased neuropil in schizophrenia [231] provided the initial impetus for the investigation of a possible role of antipsychotic drugs in schizophrenia [232]. In a review of the effects of antipsychotic drugs on neuroplasticity, these authors concluded that the ability of long-term treatment with antipsychotic drugs to induce anatomical and molecular changes in the brain may be relevant to their antipsychotic properties. Imaging studies which indicate that atypical but not typical antipsychotic drugs slow the loss of cortical volume in schizophrenia is compatible with the view that neurogenesis may be, at least, a component of the action of atypical antipsychotic drugs [233]. Preclinical studies have added some evidence for this hypothesis. Atypical but not typical APDs risperidone and olanzapine increase the number of newly generated cells in the subventricular zone [234]. Wang et al. [235] reported that three-week treatment with olanzapine but not haloperidol produced slight evidence for cortical and dorsal striatal neurogenesis but none in the NAC. They concluded that neurogenesis did not play a significant role in the effects of olanzapine on cortical function. Further study in this regard is still of interest, however.

12.18 CONCLUSIONS

Atypical APDs are those APDs which produce an antipsychotic effect at doses which cause minimal EPSs compared to typical APDs. Any other clinical feature of the atypical APDs is not part of the core definition, even if the bases for the additional clinical effect are related to the same pharmacological principles. Thus, lack of prolactin elevation is not a core feature of an atypical APD, even though it, like low EPSs, may be related to potent 5-HT_{2A} antagonism relative to weaker D₂ antagonism. The advantage to patients of having antipsychotic drugs with reduced risk parkinsonism and tardive dyskinesia are adequate reasons for making these drugs the first-line treatment for schizophrenia and bipolar disorder. There are now two established classes of atypical APDs: multireceptor antagonists which have a common serotonergic profile (e.g., clozapine) and partial DA agonists (e.g., aripiprazole). All clinically viable examples of these two classes of agents involve both a dopaminergic and serotonergic profile. 5-HT_{1A} partial agonism may be a functional substitute for 5-HT_{2A} antagonism. There is strong evidence for the role of 5-HT_{2A} receptor antagonism and 5-HT_{1A} partial agonism as a sufficient if not necessary feature of an atypical APD, in conjunction with no more than moderate D₂ receptor blockade whether it be the result of direct blockade or partial agonism. Studies are underway to determine if selective 5-HT_{2A/2C} antagonists are sufficient to treat some forms of psychosis without supplemental D₂ receptor blockade. 5-HT₆ antagonism may also facilitate some of the clinical advantages of those atypical APDs, which are potent 5-HT₆ antagonists. 5-HT_{2C} receptor blockade is a feature of some atypical APDs, but its contribution to their mechanism of action is unclear at the present time. Rapid dissociation from the D₂ receptor is not a core feature of most examples of these two classes of APDs but may contribute to the low EPS profile of clozapine and quetiapine. There are five other groups of drugs which may be atypical APDs. These include substituted benzamides, of which there are two main examples, amisulpride and remoxipride; selective 5-HT_{2A/2C} inverse agonists; D₂/5-HT_{1A} partial agonists; NK₃ antagonists; and M₁ agonists or partial agonists, of which there is only one available and that is not specific for M₁. These mechanisms of atypicality are promising and need to be further studied. There are no atypical APDs, as of yet, which have come from intensive study of D₁, D₃, or D₄ mechanisms. There are also no atypical APDs which primarily act through glutamatergic mechanisms, despite intensive effort to date to develop them and the fact that the multireceptor antagonists have been shown to act, in part, by modulating glutamatergic pathways.

13.1 HISTORY OF PHARMACOTHERAPIES

Although a few clinical and also laboratory-based research groups had addressed specific problems related to addictions from 1890 to 1964 and over that same time period a variety of different approaches, including some use of diverse chemicals as “medications,” by the early 1960s there was still no clear understanding of the bases of addictions and no consistent approach to their management, other than incarceration. Our original research team first coalesced at The Rockefeller University in very early 1964, led by Vincent P. Dole, a clinical and laboratory investigator of metabolism who up to that time had focused on hypertension and lipid disorders. Included in the group was the late Marie Nyswander, a psychiatrist who had written the very sensitive book *The Addict as a Patient*, and also this author (then a second-year postgraduate trainee having completed medical school and aimed toward a life in academic research medicine). The first task on which we focused was a definition and hypothesis related to addiction. After studying all available written materials of a variety of types and, probably more importantly, getting directly involved in interviewing scores of primarily heroin addicts, a paradigm shift in thinking very rapidly evolved. Thus, by the time we became immersed in our basic clinical research studies in the early spring of 1964 at the Rockefeller Hospital [primarily a National

Institutes of Health (NIH)–supported General Clinical Research Center], we formulated the following hypothesis: “Heroin (opiate) addiction is a disease—a ‘metabolic disease’ of the brain, with resultant behaviors of ‘drug hunger’ and drug self-administration, despite negative consequences to self and others. Heroin addiction is not simply a criminal behavior or due alone to any social personality or some other personality disorders” (paraphrased from the original research paper of 1966 covering clinical laboratory-based research performed in 1964 and presented before the Association of American Physicians (AAP) in 1966 [1, 2]. At that time, Dole decided to change his focus to the enormous social problem of heroin addiction, which he clearly saw as a medical problem with definable “metabolic” bases.

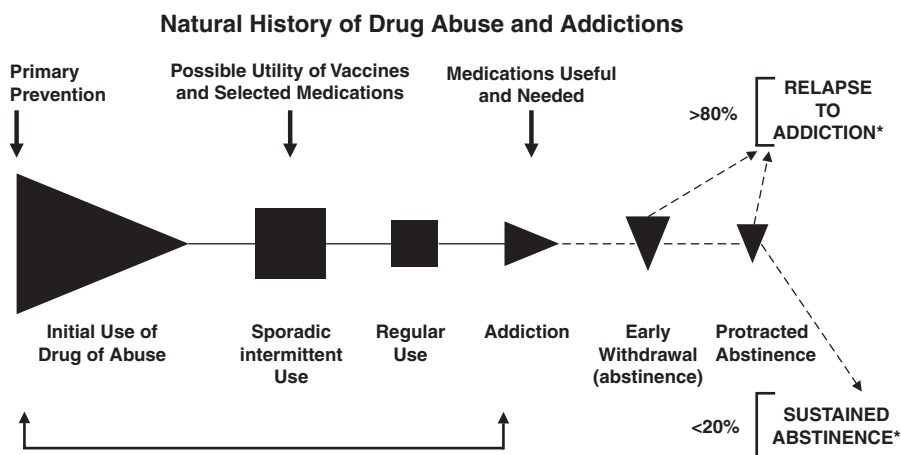

In the first few months of our research together, we had two simple goals. The first was to develop a pharmacotherapy to treat heroin addiction combined with the best behavioral therapeutic approaches, including rigorous but humane counseling as well as psychological and psychiatric and medical care as needed. The second goal was to attempt to define the physiological bases of such treatment if in fact we found one which was successful. At the time of our earliest work, there were no analytical laboratory techniques to measure plasma or even urine levels of methadone, heroin or its major metabolite morphine, or any other opiate like compound, and there were no precise molecular definitions for sites of action of these opiates. Nevertheless, it was known by qualitative work that heroin was metabolized primarily to morphine, at that time (and still) the most commonly used opioid for analgesia purposes which was administered only by parenteral (intravenous or subcutaneous) routes because of poor bioavailability after oral administration. The majority of heroin addicts used heroin by the intravenous route, although a few began use by a nasal route (“snorting”) and later by a subcutaneous route (“skin popping”) and ultimately by the intravenous route (“main lining”). These three routes of administration are still the most commonly used for many drugs of abuse, with an additional route of smoking or snorting (“freebase”). Extensive laboratory and also clinical work had been conducted on opioid analgesics. The concept of specific opiate receptor binding sites had been introduced by three groups in particular: Martin at the U.S. Public Health Service (PHS) Hospital, then in Lexington, Kentucky; Collier, in England; and our group, headed by Dole, at The Rockefeller University. All three research teams postulated that there were specific opiate receptors. The original work done to pursue that concept, from the 1960s to 1973, has been extensively reviewed, including, in part, in some of our own reviews [3–10].

In our first search for a pharmacotherapeutic agent, we wanted a medication which would be orally effective, to simplify pharmacotherapeutics; a compound with a slow onset of action, since even at that time rapid onset of action was directly related to the euphoria-producing effects of a drug of abuse (and now appreciated to be directly related to the “reinforcing” or “rewarding” effects of a drug of abuse); and a compound with a slow offset of action, to prevent the rapid precipitation of the physiological signs and symptoms of withdrawal in a tolerant and physically dependent individual, since opiates and some other addictive agents, such as barbiturates and alcohol, do produce physical as well as psychic dependence. Early on in our work, we also developed the concepts that a pharmacological agent should achieve two important therapeutic goals: first, a medication should reduce or eliminate all signs and symptoms of opiate withdrawal and, second, it should significantly reduce or eliminate all significant illicit drug “craving” and seeking and also self-administration.

There were then a very limited number of opiate analgesics approved for administration by the oral route. One of these was an infrequently used analgesic, methadone, a very simple synthetic organic diphenyl-heptanone, which had been synthesized by German chemists during World War II but which never had been studied in the clinic. When it was brought to the United States, two pain groups studied this medication and found that when delivered to opiate-naïve individuals, its duration of action with respect to analgesia was approximately the same as morphine, but further, when multiple doses of methadone were given per day, as was the practice with the short-acting available morphine, objective signs of respiratory depression began to appear, suggesting an impending opiate overdose. However, all of these studies were conducted in opioid-naïve subjects; many years later, it became fully appreciated that methadone is the opioid analgesic of choice when delivered orally in most cases of chronic pain, such as cancer-related pain, due to its long duration of action and minimal peak effects and also since it is possible to add additional short-acting opiates to sustained methadone treatment to manage recrudescence of acute pain. However, such use is done in persons receiving opiates on a chronic basis; methadone is not usually the appropriate first opiate to use in analgesia management in opiate-naïve individuals.

In a series of studies which have been published and reviewed extensively elsewhere, we found that methadone is orally effective, that beginning at low doses not to exceed 20–40 mg/day in long-term opioid-dependent heroin addicts, and then gradually increasing the doses over a period of four to eight weeks to a full treatment dose of 80–120 mg/day, no euphoric effects were noted and signs and symptoms were completely prevented [1, 2]. Further, in rigorous four-week studies, each conducted in a double-blind random-order Latin square design, we determined that a dose of 80–100 mg/day of methadone delivered orally, as just described, completely prevents all perception as well as objectively measured signs and symptoms of a superimposed short-acting opiate such as heroin or hydromorphone. In further single-blind studies, we found that to overcome this “narcotic blockade,” it is essential to superimpose 200 mg of pure heroin intravenously on the daily oral dose (80–120 mg) of methadone treatment [1–10]. During the next eight years, two different groups developed sensitive analytical techniques using gas liquid chromatography to measure plasma as well as urine levels of methadone and its metabolites. Both our laboratory and that of Charles Inturrisi published independent studies showing that the half-life in humans of racemic methadone is 24 h. (of note and importance for laboratory-based investigators, we learned in other studies that the half-life of methadone in rats is around 90 min and in mice around 60 min) [11–14].

In 1964, after the initial clinical laboratory studies, prospective studies were initiated and later special studies were carried out to determine the physiological effects, medical safety, and effectiveness of methadone; other studies were published in the early 1970s and led to the Food and Drug Administration (FDA) approval of methadone for use in the maintenance treatment of heroin and other short-acting opiate addiction by 1973 [15–19]. Later, long-term follow-up studies were conducted of a randomly selected group of methadone-maintained patients from the early treatment cohorts previously studied who had been in continuous treatment for 11–18 years [20]. Thus, the medical safety as well as physiological effects of methadone were rigorously studied from its first use, with the first subject included in data on both safety and effectiveness (reviewed in [1–10; 13–28]).

SHORT ACTING OPIOIDS: 1 in 3 to 1 in 5 who ever self-administer progress to addiction

COCAINE: 1 in 8 to 1 in 15 who ever self-administer progress to addiction

ALCOHOL: 1 in 8 to 1 in 15 who ever self-administer progress to addiction

* with no medications

Figure 13.1 Natural history of drug abuse and addictions.(Adapted from Kreek et al., *Nature Reviews Drug Discovery*, 2002.)

The regulations covering methadone maintenance treatment which were promulgated in 1973 have been modified only once, in 1983 [26]. For entry into methadone maintenance treatment, these regulations define far more severe heroin addiction than the criteria in the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) of “opiate dependence” or addiction. The federal regulation guidelines still demand that a person be regularly using heroin or another short-acting opiate daily for one year or more prior to entry in methadone maintenance treatment. In numerous laboratory models and in some careful clinical studies, it has been shown that each major drug of abuse administered on a chronic basis causes specific objective changes in the brain and brain function. Also, the relapse rate after medication-free treatment remains extraordinarily high (over 80%) in persons who have been addicted for that length of time. Therefore the Institute of Medicine of the National Academy of Sciences, after a series of extensive meetings, recommended in 1995 that the guidelines be altered to demand only six months or even less of daily self-administration prior to entry into methadone, or λ - α -acetyl methadol (LAAM), maintenance treatment [26]. This regulation, however, has still not changed, but most early federal regulations have been dropped. The previous regulation of the initial maximum daily oral dose of methadone was 120 mg/day for many years, subsequently increased to 150 mg/day and currently with no defined upper limit because of the dramatic increase in the purity of heroin. Also, office-based maintenance treatment using methadone is allowed at the federal level now; the only provision is that initially addicts have to be admitted by a standard opioid treatment clinic, that is, a methadone maintenance or other clinic configured by the original methadone guidelines prior to transferral to a doctor’s office for continuing care. However, the duration that subjects have to be in such an organized clinic and the

achievements made in their steps to recovery have not been defined. We have reviewed these recent guidelines elsewhere [15]. These regulations are still far more restrictive than those which currently pertain for another opioid partial agonist treatment, that is, treatment with the partial agonist buprenorphine, with or without the combination of naloxone.

Overall, at this time, there are approximately 212,000 persons in methadone maintenance treatment in the United States and over half a million worldwide. The voluntary retention in good clinics which use adequate doses of methadone (usually 80–150 mg/day), along with adequate counseling and psychological and psychiatric care remains over 50%, with excellent clinics still achieving over 80% voluntary retention at one year [3, 4, 9, 10, 29]. The actions of methadone treatment were early established to include prevention of withdrawal symptoms and reduction or elimination of “drug hunger” or drug craving. It was established in early clinical laboratory studies and reproduced by many groups over the last 40 years that methadone blocks the euphoric effect of superimposed short-acting narcotics. Also, further studies, including our prospective and special medical studies and medical safety and many subsequent studies, have shown that steady-dose methadone treatment allows normalization of physiology disrupted by long-term heroin use. The mechanism of action was hypothesized and then established by the time the specific opiate receptors were clearly defined to exist in 1973. It was established by then newly developed analytical techniques that methadone provides steady levels of this opioid at the specific opiate receptor sites. Subsequent work in the 1970s established that there are μ -opioid receptors where heroin, morphine, and methadone primarily act. More recent work by several groups have shown that methadone is a full μ -opioid agonist, not a partial agonist, and further that after binding to μ -opioid receptors methadone undergoes immediate internalization bound to the receptor, similar to the physiological handling of β -endorphin, enkephalin, and other μ -opioid receptor-directed

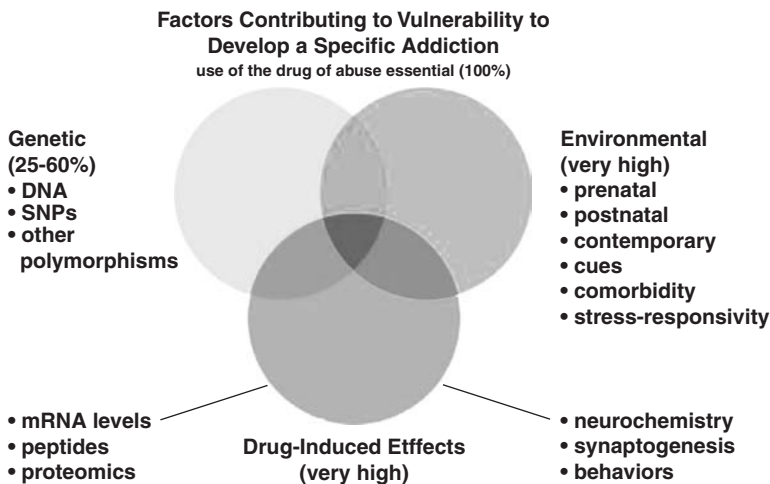

Figure 13.2 Factors contributing to vulnerability to develop a specific addiction. (Adapted from Kreek et al., *Nature Reviews Drug Discovery*, 2002.) (See color insert.)

endogenous opioids. This is in sharp contrast with most exogenous synthetic or natural plant opioids, which bind to the receptors but then prevent the receptor from rapidly internalizing. In addition, it has been shown both in laboratory studies and more recently in human studies that the two enantiomers of methadone have modest *N*-methyl-D-aspartate (NMDA) receptor antagonism which would be expected to slow or attenuate the development for opioid tolerance. Our early stable isotope mass spectrometry research showed that the two enantiomers of methadone are metabolized at very different rates, with the active enantiomer l(R) having a half-life of over 36 h in humans and the inactive d(S) enantiomer having a half-life of around 16 h, findings confirmed more recently by several groups. In contrast, it has been shown that heroin has a half-life of only 3 min in humans. Its first and active metabolite, 6-acetyl-morphine, has a half-life of 30 min in humans, and its major metabolite, morphine, and its major active metabolite, morphine-6-glucuronide, have half-lives of 4 and 6 h, respectively (reviewed in [4, 9, 10, 13, 15, 16]).

Several other pharmacological treatments for opiate addiction have been developed, including LAAM, a full agonist which is biotransformed to two active metabolites conferring an even longer half-life in humans than methadone, and buprenorphine, a μ -opioid receptor partial agonist which must be administered sublingually because of its essentially complete “first-pass” effect, that is, biotransformation by the liver after oral administration, and also an opioid which gives a rapid onset of action if used or abused by a parenteral route. This led to the development of a better sublingual formulation, combining buprenorphine with naloxone, which has no adverse effect when administered by this route but would blunt the peak effects of buprenorphine if this formulation were abused in a parenteral route. Each of these compounds has been studied extensively and is effective in the long-term, maintained management of heroin and other slow-acting opiate addiction. However, the maximum dose of buprenorphine which gives any increased opiate effect in humans, because it is a partial agonist, is around 24–32 mg sublingually, equivalent to a maximal 60–70 mg of methadone, a lower dose than shown in many studies over 40 years to be essential for most unselected heroin addicts. The use of each of these compounds in treatment of heroin and other opiate addiction has been reviewed in many articles and will be addressed in Chapter 19 (reviewed in [8, 10, 13, 15, 16, 30]).

Figure. 13.1 presents a history of the development of drug abuse and drug addiction after first self-exposure. It has been well established that primary prevention can be extremely effective, but it is most effective prior to any initial use of a drug of abuse. In the future, vaccines of a variety of types (several now under development specifically for nicotine, cocaine, and heroin) and also some selected medications may have possible utility after the initial sporadic, intermittent use of a drug of abuse occurs. However, regular use, although continuing in only a limited proportion of those who initiate use of a drug of abuse, leads in most cases to addiction. At that point, medications are useful and, in fact, needed. If no targeted specific medications are available, repeated studies over the past 70 years (such as the first outcome studies performed at the PHS facility for opiate addicts in Lexington, Kentucky, after its opening in the mid-1930s) have shown that over 80% of persons meeting any established national (e.g., DSM-IV) or international criteria for addiction will ultimately relapse to an addiction and, in most cases, to the specific initial predominant addiction. Again, according to repeated studies in which the proper denominator is

used, that is, all persons entering into any form of management or treatment, less than 20% will respond with sustained abstinence to drug-free, medication-free treatment for one year or more. Therefore, targeted specific medications are needed, and, further, many studies have shown such medications are most effective, by far, when administered in conjunction with behavioral treatments, including counseling and psychological or psychiatric care, as needed (e.g., [4, 5, 8–10, 15, 16, 26, 28–35]). Reviews of many different epidemiological studies over the years as well as our own meta-analyses have shown that approximately 1 in 3 to 1 in 5 who ever self-administer a short-acting opiate, such as heroin, will progress to addiction; approximately 1 in 8 to 1 in 15 who ever self-administer cocaine will progress to cocaine addiction, and roughly 1 in 8 to 1 in 15 who ever self-administer alcohol will progress to alcoholism (see Fig. 13.1 [in 16]).

The chapters in this section will address specific drugs or classes of drugs. In each case, what is known about the nature of each addiction at a molecular, neurobiological, behavioral, and/or global level will be discussed followed by proven or projected interventions with a focus on pharmacotherapeutic interventions either available now or under various stages of development. The chapters will focus on a specific type of addiction, including alcohol abuse and addiction, nicotine abuse and addiction, psychostimulant abuse and addiction, 3, 4 methylenedioxymethamphetamine (MDMA [“Ecstasy”]) and other “club” drug abuse and addiction, and marijuana abuse and addiction.

13.2 VULNERABILITY TO DEVELOP A SPECIFIC ADDICTION

We have defined three domains of factors which may contribute to developing a specific addiction (see Fig. 13.2). These include personal factors such as comorbidity with psychiatric or medical illnesses and also responsivity of an individual along with prenatal and postnatal events, contemporary events, cues or set and setting, and environmental factors. The second domain comprises drug-induced factors; we hypothesized in the mid-1980s that each drug of abuse would profoundly alter molecular events in the brain. Our laboratory and many others worldwide now have joined in an effort which has clearly defined that each major drug of abuse, when administered on a chronic (though usually not acute) basis and in an addiction-like pattern or mode, will cause significant and persistent changes in the brain, including messenger RNA (mRNA) levels, resulting peptides, proteomics, integrated neurochemistry, synaptogenesis, possibly even neurogenesis, and resultant behaviors. Further, our group and others have shown that although many acute effects occur, many of these rapidly disappear and new alterations occur after subacute or chronic administration, some of which may be long-term persistent (or possibly permanent) after cessation of exposure to a drug of abuse. Third and finally, it has been clearly shown that genetic factors play a role and make a 25–60% contribution to the risk for development of specific addictions, as well as any addiction. These genetic factors undoubtedly will include a variety of single nucleotide polymorphisms (SNPs) and other types of polymorphisms of many genes acting in concert to increase vulnerability to develop addiction [36–46]. Essentially all investigators in the area hypothesize that addictions will be complex, not just simple, genetic disorders, that is, involving multiple variants of multiple genes. Moreover, it should be clearly understood that different individuals will have different combinations of these gene

variants, in part due to the profound allelic frequency differences of many variants in different ethnic groups, in part due to genetic factors contributing to comorbidity, including differences in drug metabolism as well as psychiatric and some types of medical comorbidity, and in part, because many of the variants will ultimately be shown to be functional, may have very different kinds of impacts on the resultant peptides. Gene variants could include actually changing peptide structure if the gene variant is in the coding region of a gene, or altering amounts of message, and therefore peptide amounts produced, especially if the variants are in critical locations of the 5' promoter region as well as certain intronic and 3' regions. Thus, environmental, drug-induced, and genetic factors all may contribute to the vulnerability to develop a specific addiction in an individual (see Fig. 13.2). These changes have been discussed in detail in many recent and earlier review articles ([3, 4, 6–10, 14, 16, 24, 25, 27, 28, 31–34, 36–59]).

13.3 REWARD, MODULATION, AND COUNTERMODULATION OF REWARD AND THEIR ROLE IN SPECIFIC ADDICTIONS

It has been well established by innumerable groups that drugs of abuse have rewarding or reinforcing effects in the context of use which strengthen the perception and, more importantly, the memory of euphoria or pleasure. In addition, each of these effects uses some natural molecular–neurobiological neurotransmitter or transporter systems, including established neural pathways. However, distortions develop in both the absolute and relative amounts of each neurotransmitter, receptor, and downstream single-transduction event component as well as the neuropathways, and possibly synaptogenesis and neurogenesis get altered in the development of “reward,” with the associated processes of learning and memory. The natural modulators of each of these systems begin to play a role and they too may become exaggerated, leading to countermodulation of the so-called “rewarding” effects of each drug of abuse, which also contributes to the abnormal status which often persists in the drug-free and medication-free state.

Using a variety of models, much work has been done worldwide on what may be the specific components of both reward, and modulation and countermodulation of reward. Clearly, the majority of studies have pointed to the intermediate-acting monoamine neurotransmitter dopamine as being central to reward. However, two other monoaminergic systems, the serotonin and norepinephrine systems, have been shown to be also involved. Our laboratory and many others have also shown unequivocally that the μ -opioid receptor system is involved in reward. There are increasing numbers of studies showing that whereas for some drugs of abuse the dopaminergic system may dominate, for other drugs of abuse the μ -opioidergic system may predominate. Further, it has been shown that the dopaminergic system is involved in some of the effects of all drugs of abuse, but, unexpectedly, our group and others have shown that the endogenous μ -opioidergic system is also involved to a certain extent in most, if not all, of the rewarding properties of drugs of abuse (reviewed in [6–9, 14, 16, 24, 27, 28, 32–34, 36, 38–41, 44]).

Immediate modulators include the usual rapid-acting and stimulatory neurotransmitter systems, including, but not exclusively, the γ -aminobutyric acid (GABA)–ergic and glutamatergic systems, as well as the much slower neuropeptide

cannabinoid systems and others. However, distortion of these systems also occurs. Our group and others have shown that the natural dynorphin opioid peptides acting at the κ -opioid receptors play a major role in countermodulation through their ability to reduce dopaminergic tone. Similarly, orphanin-nociceptin FQ, acting at its specific opioid-like but non-opioid receptors, plays a role similar to that of dynorphin acting at the κ -opioid receptors, with modulation of dopaminergic tone. Further, this latter system has also been shown to alter stress responsivity (see below).

One of the initial hypotheses of our laboratory was that an atypical response to stress and stressors may contribute to the persistence of and relapse to a specific addiction, and further, in some individuals, atypical stress responsivity existing a priori on a genetic or environmental basis may contribute to the initial acquisition of an addiction [6, 9, 10, 14, 18, 19, 21, 24, 25, 28, 47–51]. Many studies from our laboratory in humans, including genetics studies as well as basic molecular neuroendocrine studies, have given strong support to this hypothesis. Similarly, in work from our laboratory and innumerable other laboratories, using a variety of animal models, it has been shown that stress responsivity plays a central role both in the acquisition of drug abuse and in the relapse to self-administration or “reinstatement” of drug abuse. Again, these studies have been reported in both early and very recent papers from our laboratory and in some of our review articles [47–59].

Therefore the rewarding or reinforcing effects of drugs of abuse coupled with modulation and countermodulation in the context of specific environments and the specific genetic fabric of each individual and especially with the predictable chronic drug effects which may persist after drug use has ceased all contribute to the acquisition, persistence and perpetuation of an addiction, and some contribute to learning and memory and thus behaviors in the medication-free, drug-free state, despite aggressive counseling and behavioral treatments. These persistent changes in the brain and resultant behaviors may lead to relapse and thus perpetuation of addiction; these topics will be considered in the chapters that follow. Each site of action and alteration provides potential targets for pharmacological intervention as well as increasingly selective behavioral interventions. However, it is now clear that specific pharmacotherapies will be needed for most persons suffering from specific addictive diseases.

ACKNOWLEDGMENT

Funding support was received from the National Institutes of Health—National Institute on Drug Abuse Research Scientific Award Grant K05-DA00049, the National Institutes of Health—National Institute on Drug Abuse Research Center Grant P60-DA05130, the National Institutes of Health—National Center for Research Resources (NCRR) General Clinical Research Center Grant M01-RR00102, and the New York State Office of Alcoholism and Substance Abuse Services. I would also like to thank Susan Russo for help with preparation of the manuscript.

14.1 INTRODUCTION

Over the past two decades it has become increasingly clear that the disease of alcoholism, like other substance abuse addictions, is a brain disorder. Thus, one of the key objectives of alcoholism research is to understand the neuroanatomical substrates and neurocircuitry within the brain regulating alcohol addiction and dependence in humans. Unfortunately, alcoholism in humans is a complex disorder comprising not only central nervous system (CNS) mechanisms [1] but also social, cultural, and emotional influences [2]. Through basic neuroscience research, scientists in the alcohol field, particularly researchers focused on alcohol self-administration [3–9], are gaining a better understanding of the neuromechanism(s) regulating alcohol drinking behavior. This success has largely been attributable to the development and use of animal models [1].

14.2 OPTIMAL ANIMAL MODEL TO STUDY NEUROANATOMICAL SUBSTRATES OF ALCOHOL SELF-ADMINISTRATION BEHAVIORS

Animal models of alcoholism have provided useful analogs of the human condition, and a number of researchers have employed these models to study the neurobiological

factors mediating alcohol self-administration. As noted by Li (see [1], p. 36), such models are useful only “when they reveal some aspects of the complex process to yield understanding about the human condition.” Thus, to model the human condition, with specific considerations of criteria of alcoholism of the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV), genetically selective breeding of rats that initiate excessive alcohol drinking has produced an unequivocal impact in the field of alcoholism research. Exemplary of the genetically selected rodent is the alcohol-preferring (P) and high alcohol drinking (HAD) rat lines developed by Indiana University’s Alcohol Research Center. One of the primary criteria for an animal model of alcoholism [10], similar to the DSM-IV criterion in humans, is that individuals/rodents will work at high levels to obtain alcohol and that a great deal of time is spent in activities necessary to obtain alcohol. This criterion for alcoholism attests to the reinforcing strength/efficacy of alcohol as an abused substance. In comparison to most genetically selected rodent models of alcohol drinking, the efficacy profile of the Indiana selected rat models, particularly the P line in the operant paradigm, far exceeds that of the other rodent models (see [4, 11–13]). Thus, to model the human condition of alcohol abuse, in the present review, we have primarily selected as subjects the P rats, and the HAD rats to a lesser degree. Further, the P rat line has been shown to satisfy most of the criteria for an animal model of human alcohol abuse [10] to the satisfaction of the alcohol research community [8]. While the criteria have been discussed at length in the excellent review by McBride and Li [1], a brief summary of these findings is warranted to provide the reader with the rationale for using the P rat as subjects in the study of neurobiological mechanisms underlying alcohol self-administration behaviors. Other summaries in relation to the P rat line as an optimal model of the human condition of alcoholism/abuse can also be found in the literature [3, 8, 11]. Nevertheless, the P rat will: (1) voluntarily consume 5–8 g/kg of alcohol to attain blood alcohol concentrations of 50–200 mg%; (2) lever press for alcohol orally in concentrations of 10–40%, despite the fact that water and food are concurrently available; (3) drink alcohol for its pharmacological effect and not solely because of its taste, smell, or caloric properties as evidenced by self-administration of alcohol intragastrically and intracranially by P rats; (4) develop both metabolic and functional tolerance with free-choice alcohol drinking; and (5) develop physical dependence and signs of withdrawal following removal of alcohol after periods of chronic consumption. Taken together, the P rat line is among the best, albeit not perfect, models of human alcoholism [1].

14.3 INTEGRATING P RAT LINE WITH APPROPRIATE BEHAVIORAL PARADIGMS AND NEUROANATOMICAL STUDIES TO MAKE INFERENCES ABOUT NOVEL NEUROANATOMICAL SUBSTRATES OF ALCOHOL SELF-ADMINISTRATION BEHAVIORS

14.3.1 Appropriate Behavioral Paradigms

A variety of procedures have been successfully used to motivate rodents to orally self-administer alcohol [4]. The most widely used and accepted method in the alcohol field, particularly with outbred rats, is the sucrose-fading technique developed by Samson [14, 15]. Over the years, researchers have validated as well as modified this procedure for both limited (e.g., 10–60 min) and more prolonged exposure periods

(e.g., 2–4 h) [15, 16]. Modifications to the procedure wherein non-food- and water-deprived rats trained to initiate ethanol (EtOH) responding are allowed to obtain water or EtOH by responding at one of two levers have produced an operant choice paradigm that can be used to investigate the neuropharmacological bases of alcoholism [4, 17]. Other modifications of the procedure include a two-lever design wherein nondeprived rats lever press for alcohol on one lever and a highly palatable/isocaloric solution on the other (see [18, 19]). Some of the important features incorporated in this model include: (a) maintenance of responding for EtOH as a measure of EtOH reinforcement; (b) an index of preference for EtOH over water, independent of the absolute amounts of EtOH consumed; (c) a control for nonspecific drug effects on ingestive behaviors; (d) dissociation of the pharmacological motivation from consummatory processes; and (e) measurement of significant blood alcohol concentration (BAC) levels (see [4], also [17]).

In addition to the sucrose-fading technique, a number of laboratories have developed other procedures wherein pharmacologically relevant EtOH concentrations are obtained after training rats to orally ingest alcohol. Such techniques have been used in the home cage with both outbred rats [20–22] and rats selectively bred for alcohol consumption [1, 8]. For example, the ascending two-bottle water choice [20, 21] and the sweetened cocktail solution procedures [22] have been reported to produce EtOH intake levels in outbred rats that result in pharmacologically relevant EtOH concentrations. In addition, variations in the 24-h home cage model using limited-access procedures (e.g., 30–240 min) have been quite effective in producing significant alcohol levels and have been employed extensively in studying the neurobiological mechanisms of alcohol drinking, even in alcohol selectively bred rodents (Ps, HADs) [23–26]. Unfortunately, the investigator has little control over the contingent relations between responses and ingestion in this home cage model. Roberts and colleagues [27] suggested employing the home cage as the only reinforcing model “is potentially confounded by palatability.” As in studies of other abused drugs, the most appropriate instrument is the operant conditioning chamber where the contingency between responding and drinking can be specified and the volume of liquid ingested per completed schedule unit can be controlled. The operant methodology is especially important in analyzing complex dose–response relationships of a test agent [28, 29] and when examining the effects of a test agent on EtOH and another concurrently available reinforcer [5, 28, 30–33]. Finally, when the 24-h access model is employed, it is difficult to determine pharmacologically relevant BACs, since the scheduled drinking bout(s) is often difficult to ascertain. BACs are important when trying to determine the neuromechanism of action of EtOH [34–36]. Hence, the operant paradigm has a number of advantages over simple home cage drinking procedures in rats and mice [4, 27].

As noted above, the most widely used and accepted method of initiating operant responding for alcohol drinking in outbred and alcohol selected rats is the sucrose-fading technique [14]. The merits of this initiation procedure have been discussed in several previous reviews [1, 4]. However, while a number of laboratories are currently evaluating the efficacy of pharmacological treatments on scheduled controlled responding using the Samson procedure, studies in which specific controls are used for rate dependency and the postingestional properties of the test solutions are generally lacking in the alcohol literature. As a result, many published reports are very difficult to interpret in relation to the selectivity of a test agent reducing alcohol

drinking on the one hand, and the degree to which inferences can be made from these studies to neural mechanisms of action on the other. It is important to note that selectivity for alcohol drinking is a very important concern in self-administration studies given that most studies in the literature report that test compounds “all” reduce motivated responding for alcohol. Elevations in alcohol-motivated behaviors, particularly within the operant chamber in non-food- or water-deprived rodents, have generally not been reported in the alcohol literature. Thus, to eliminate confounding of results/interpretation, it is important to use *rigorous reinforcer control procedures* in alcohol self-administration research. While a thorough review of these procedures is beyond the scope of this chapter, below we provide a brief review of protocols that can be used to optimize data interpretation in rodent alcohol-self-administration research. For more details on these procedures, the interested reader should consult the protocols outlined in June [4].

14.3.1.1 Reinforcer-Specific Controls. First, to investigate the capacity of a pharmacological agent to produce dose and time course effects when rats are presented with EtOH as the sole reinforcer, rodents should be given the EtOH solution on a fixed-ratio (FR) schedule, preferably an FR4 or FR6. Second, the capacity of a pharmacological agent to produce dose and time course effects when rats are presented with a palatable reinforcer (e.g., saccharin, sucrose) as the sole reinforcer on an FR schedule should also be determined. When the data are interpreted, one is able to make inferences as to whether antagonism is specific to EtOH-motivated behaviors. Third, the researcher should evaluate the capacity of a pharmacological agent to produce dose and time course effects when a concurrent schedule procedure is employed under an FR schedule [37]. Because basal response rates should be equal or near equal between groups in this protocol, the concurrent schedule will address the issue of whether the capacity of an agent to decrease EtOH and not saccharin reinforcement is due to differences in reinforcing efficacy (i.e., strength). Finally, the capacity of a pharmacological agent to produce dose and time course effects under a concurrent FR schedule procedure when two isocaloric alternative solutions are presented should be evaluated. The caloric consideration is important insofar as the calories contained in alcohol could contribute substantially to its motivating properties [32], independent of the CNS pharmacological effects. It should also be noted that Bodnar and his colleagues [38, 39] have reported a differential regulation of caloric compared with noncaloric reinforcers within the opioid systems. Thus, the CNS substrates which regulate a particular type of palatable ingesta may be different. It is well established that an isocaloric concurrent procedure for alcohol and the alternative solution may produce different response rates and profiles (see [40]).

14.3.1.2 Neuroanatomical Controls. Although reinforcer-specific controls add immensely in making inferences about pharmacological probes in investigating neuroanatomical substrates of alcohol-motivated behaviors, equally important is the use of neuroanatomical controls. Such studies are rarely performed in published reports in the alcohol field. CNS substrates are primarily studied in alcohol research using microinjection procedures (i.e., intracerebral drug delivery) [1, 9]. Generally, there are two types of neuroanatomical control groups that will assist in data interpretation (see [4]). First, a researcher may use a “region-specific” control wherein a second infusion is performed 1–2 mm away from the designated brain site. The second

infusion may be given rostral, caudal, ventral, or dorsal to the designated brain site. Studies that attempt to compare the anterior and posterior ventral tegmental area (VTA) or the nucleus accumbens (NAcc) shell and core or the NAcc and ventral striatum are also examples of “region-specific” comparisons. For illustrative examples of such control procedures, studies by Nowak et al. [41] and June et al. [19, 29] should be reviewed. Alternatively, a researcher may also use an entirely different locus as the control site. This type of control is referred to as an “alternate region” control. The alternate region control is particularly important when different receptor populations or subunit configurations are of interest. Such controls are illustrated in the work by Eiler et al. [42] wherein the caudate putamen was used as an alternative locus in investigating the dorsal bed nucleus of the stria terminalis. Harvey et al. [37] also used the alternate region design wherein the NAcc and caudate putamen were used as control loci in investigating the ventral pallidum, a putative drug reward substrate ventral to the NAcc [43].

In summary, this section has provided information pertaining to the P rat as a model of alcoholism. The model has a number of advantages over other currently available models, and with the exception of variables relating to psychosocial and cultural factors which influence drinking, the P rat satisfies the DSM-IV criteria reasonably well for the condition of alcoholism in humans [1]. Besides having an “optimal animal model,” both reinforcer (i.e., pertaining to ingesta) and neuroanatomical control procedures were discussed and suggested to be critical in making direct inferences about putative neuromechanisms of alcohol-motivated behaviors. We propose that integration of the ideal animal model combined with systematic utilization of reinforcer and neuroanatomical specific control designs is a multidisciplinary approach which provides a researcher with a wealth of data for systematic evaluation and interpretation of pharmacological probes to understand the neuromechanisms regulating alcohol-motivated behaviors.

14.3.2 Role of CNS Circuitry in Mediating EtOH Self-Administration

An understanding of the neuroanatomical substrates, neurocircuitry, and interaction of the neuronal systems which regulate alcohol drinking is key in the identification of novel targets for drugs to treat alcohol addiction and dependence in humans [19, 37, 44]. While alcohol affects an array of neuronal systems, including opioids, glutamate, γ -aminobutyric acid (GABA), adenosine, serotonin, and the catecholamines [1, 45–47], alcohol also shares common neural substrates, circuitry, and characteristics with other addictive substances. Specifically, alcohol shares the property of increasing dopaminergic activity in the mesocorticolimbic system [48]. Within the mesocorticolimbic system, previous research focused on the VTA of the midbrain and its projection to the limbic forebrain, the NAcc (for a review see [46]). Indeed, prior work in animal models and humans provides evidence that all drugs of abuse converge on this pathway to produce their reinforcing effects ([49]; for a recent review see [50]). However, as discussed in a recent review by Lovinger and Crabbe [44], alcohol abuse and alcoholism have a number of distinct neuronal processes from other substance abuse disorders. For example, recent work has demonstrated that a number of additional brain areas independently or in collaboration with the VTA and NAcc play an important role in regulating alcohol drinking behaviors [46, 51, 52]. Specifically, regions of the extended amygdala circuit [central nucleus of the

amygdala, bed nucleus of the stria terminalis, shell of the NAcc, sublenticular substantia innominata (SI)/ventral pallidum] [53, 54], hippocampus, and lateral hypothalamus have all been shown to regulate alcohol drinking ([30, 42, 55, 56]; also for a review see [19]). As noted by Nestler [50], because some of these areas are associated with the traditional memory system, the study of these new substrates could provide information about the cognitive factors and emotional memories which might regulate alcohol drinking and relapse behavior. In addition, because brain areas such as the hypothalamus may play a role in alcohol addiction as well as the so-called natural addictions (e.g., obesity, sex) [57, 58], these areas could provide strategies to understand the common/shared neuronal pathways which regulate the behavioral pathology of alcohol and other consummatory behaviors.

14.3.3 Novel Neuroanatomical Substrates Regulating Alcohol Reward

Research on the substrates and circuitry regulating alcohol self-administration has experienced an enormous growth over the past decade. Several reviews have described this area of inquiry [1, 8, 9, 59]. In many cases, these reviews have provided an exhaustive coverage of the neuronal substrates and systems which have been shown to regulate alcohol-motivated behaviors. In the present review, we will focus exclusively on relatively new findings in the alcohol self-administration literature (many of which were not available or omitted in prior reviews), implicating novel substrates and circuitry within the dopaminergic and GABAergic systems. The *majority* of the recent studies described here have employed rigorous reinforcer and neuroanatomical specific control designs, allowing for more precise inferences about putative alcohol reward mechanisms. The focus on the dopamine (DA) and GABA systems relates to both neuroanatomical topography and established neurochemistry, demonstrating that within several loci in the CNS a neuromodulatory role may exist between the two systems. New findings will be presented demonstrating that exploitation of the GABAergic system indeed represents a vital strategic route for the development of novel prototype ligands to reduce alcohol drinking behavior in human alcoholics. Moreover, we propose that GABA mediates its actions on alcohol self-administration via interaction with the DA system [19, 37]. Hence, in this regard, a review of the literature pertaining to DAergic regulatory control on alcohol self-administration is warranted. Finally, it is clear that a number of other important neuronal systems have been shown to be important in regulating alcohol reward mechanisms, particularly imbalances in corticotropin-releasing factor (CRF) and neuropeptide Y (NPY) [60–63]. A discussion of this literature is beyond the scope of the present review.

14.4 DOPAMINE NEURONAL SYSTEMS AND SUBSTRATES REGULATING ALCOHOL REWARD

According to the DA hypothesis of reward, DA systems directly mediate the rewarding or primary motivational characteristics of natural stimuli such as food, water, and sex as well as various drugs of abuse, including EtOH [57]. The most current research examining the role of DA in the reinforcing properties of EtOH has focused on the interactions of the NAcc and the A10 DA cell body grouping known

as the VTA (for a review see [51]). The NAcc receives its extensive DA innervation from the VTA. This DAergic fiber tract is referred to as the mesolimbic pathway (for a review see [64]). Below, we provide a selective review of the early systemic, site-specific microinjection and lesion studies that have been critical in providing support for a dopaminergic regulation in alcohol self-administration research.

14.4.1 Dopaminergic Regulation in Alcohol Self-Administration: Review of Previous Research

A body of research employing systemic injections has implicated DA neurotransmission in alcohol reinforcement. Generally, this research has demonstrated that neurochemical manipulations which increase DA transmission increase EtOH intake and responding, while manipulations that reduce DA transmission reduce responding and intake; however, conflicting reports have emerged (for a review see [1, 9, 17, 51]). Initial studies employing site-specific microinjection methodology evaluated the effects of bilateral infusions of the D₁ antagonist SCH 23390 (0.1–2.0 µg/side) and the D₂ antagonist sulpiride (0.1–2.0 µg/side) into the NAcc of P rats during a 30-min home cage EtOH access period [65]. The D₂ antagonist sulpiride produced a significant dose-dependent increase in alcohol drinking, while no significant effects were seen with SCH 23390. Subsequent studies by Samson and his colleagues [9, 66, 67] have shown that bilateral intra-accumbens infusions of the nonspecific agonist *d*-amphetamine (4–20 µg) or the more selective DA D₂-like (i.e., selectivity toward D₂ compared to D₃ and D₄) agonist quinpirole (1 µg) increased EtOH responding in outbred rats. In this same study, however, higher quinpirole doses (4 and 10 µg) significantly decreased EtOH responding. Samson and his colleagues have also shown that reducing DA neurotransmission in the NAcc directly by local administration of the D₂-like antagonist raclopride [9] or indirectly by infusion of the D₂ agonist quinpirole [66] into the VTA decreased EtOH responding. It should be noted that quinpirole in the VTA inhibits DA cell activity via a proposed feedback of the cell upon itself [68]; hence, it would be predicted that quinpirole would produce effects similar to blockade of DA neurotransmission in the terminal field by raclopride. Indeed, Murphy and his colleagues (see [41]) demonstrated that direct infusion of quinpirole as well as another D₂ agonist quinlorane in the VTA of P rats reduces home cage alcohol but not saccharin drinking. It should be noted that a selective reduction on alcohol was observed in the anterior, but not the posterior, VTA, suggesting that only those D₂ receptors on cell bodies within the anterior VTA selectively regulate alcohol intake [8]. One hypothesis that has been used to explain the effectiveness of DA agonists in decreasing EtOH self-administration is that agonists blunt the reinforcing actions of EtOH by substituting for the DA-enhancing action of the agent. The heightened “hedonic state” produced by DA receptor activation may eliminate the rats’ motivation to respond for EtOH [69, 70].

In addition to the pharmacological microinjection studies discussed above, substantial neurochemical evidence supports a role of the mesoaccumbens DA system in mediating EtOH-motivated behaviors [71–73]. These relatively recent neurochemical studies are discussed below. However, not all studies support a direct role for the DA system in alcohol self-administration. Specifically, early neurobehavioral studies with neurotoxic lesions [74–76] suggested that norepinephrine (NE) may play a more important role than DA in EtOH self-administration. Pharmacological manipulations

using highly selective DA receptor agents have also failed to alter EtOH self-administration [77]. Nonetheless, it should be noted that these studies used systemic administration, not examining discrete brain loci. Previous work by Rassnick et al. [78] have shown that 6-Hydroxy-Dopamine (6-OHDA) lesions of the NAcc do not block established oral EtOH-reinforced responding on a continuous reinforcement schedule. Rassnick and her colleagues have interpreted these data to mean that the mesoaccumbens pathway is not the only system involved in mediating EtOH reinforcement. Research involving the infusion of DA agonists and antagonists into the NAcc is also equivocal. For example, while Samson and his colleagues demonstrated that DA antagonists infused in the NAcc decrease EtOH-reinforced responding [67], dose-dependent increases were observed by Levy et al. [65] with DA antagonists. While this discrepancy has not been resolved in the current literature, one possible explanation to account for these findings is that altered responses to DA blockade in P rats might result from neurobiological changes in DA systems and cause P rats to initiate rather than suppress responding/intake [1].

14.5 NOVEL DOPAMINE SUBSTRATES REGULATING ALCOHOL REWARD

More recent research has begun to focus on brain substrates other than the NAcc that are innervated by the VTA. Many of these loci have been shown to play a role in mediating the rewarding properties of multiple drugs of abuse [79]. This section examines recent evidence that implicates these new loci in the regulation of EtOH reward. For each locus reviewed, the effects of EtOH on the DA system within the substrate will be discussed, as will any effect DA manipulation has on the mediation of EtOH reinforcement. The first substrate to be discussed is the bed nucleus of the stria terminalis (BST) a forebrain structure innervated by DA within the VTA [80]. The second structure examined is the ventral pallidum (VP), a ventral forebrain structure that receives dopaminergic input from the VTA via the mesopallidal pathway [81, 82]. The final substrate, the lateral hypothalamus (LH), is best known for its control of feeding and drinking behavior [83–85]. It receives innervation from DA neurons originating within the VTA via the mesothalamic pathway [64, 86].

14.5.1 Bed Nucleus of Stria Terminalis

Recent evidence has emerged suggesting that the BST exerts dopaminergic control over the reinforcing properties of EtOH [42, 48]. The BST is perhaps best known as a component of the extended amygdala (EA), a group of forebrain nuclei that exhibit similar morphology, immunoreactivity, and connectivity (including the NAcc shell, central nucleus of the amygdala, and substantia innominata) [53]. As with other members of the EA, the BST receives extensive dopaminergic innervation from the DA cell bodies located within the VTA via the mesolimbic path [87, 88]. DA input from the VTA is received within the BST by a 3:2 ratio of D₁-like to D₂-like DA receptors [80, 89, 90]. Within the BST, several other neurotransmitters (e.g., GABA, glutamate, and various opioid peptides) also facilitate neuronal communication to the other putative alcohol reward substrates of the extended amygdala, such as the NAcc and central nucleus of the amygdala (CeA), as well as other reward areas outside the

EA, such as the VP and the hippocampus [80, 87, 88, 91–93]. The BST has also been found to send GABAergic connections back to the VTA, perhaps to regulate the VTA dopaminergic output [94, 95].

The first study examining the role of the dopaminergic system within the BST on acute EtOH administration was conducted by Carboni and colleagues in 2000 [48]. In this study, Carboni et al. examined DA release in the BST following peripheral administration of various drugs of abuse. To accomplish this, a microdialysis probe was implanted in the anterior BST of male Sprague–Dawley rats. After the recovery phase, the rats were given systemic cocaine, the selective DA reuptake inhibitor GBR12909, morphine, nicotine, and alcohol (0.25 and 0.5 g/kg) (see Fig. 14.1). Their data demonstrated that all drugs led to significant increases in extracellular DA in the BST, lending increased support for a role of the BST in the mediation of drug reward. It should be noted that the 0.25- and 0.5-g/kg alcohol doses represent levels that are obtained during alcohol responding and intake [4]. In addition, these doses typically induce locomotor activation in rodents [96, 97], particularly during the ascending limb of the BAC [96]. Hence, to the extent that the locomotor activational effects in rodents may be a putative model of alcohol-induced euphoria in humans [97, 98], the findings by Carboni and colleagues could have relevance to alcohol's rewarding properties. Nevertheless, Carboni and colleagues [48] suggested that the EtOH-induced increase of DA in the BST might be analogous to the DA release in the NAcc.

While the Carboni et al. study was the first to suggest the DA system within the BST may be involved in EtOH reward, this study obviously does not directly test the

Figure 14.1 Effect of ethanol following intraperitoneal injection of 0.25 and 0.5 g/kg (injected as 10% v/v solution) on dopamine concentration in dialysate obtained by in vivo microdialysis from BST. Each point is the mean [standard error of the mean (SEM)] of at least four determinations. Filled symbols: p , 0.05 from basal values concentration; (*) p , 0.05 from corresponding time point of vehicle group. Adapted from [48].

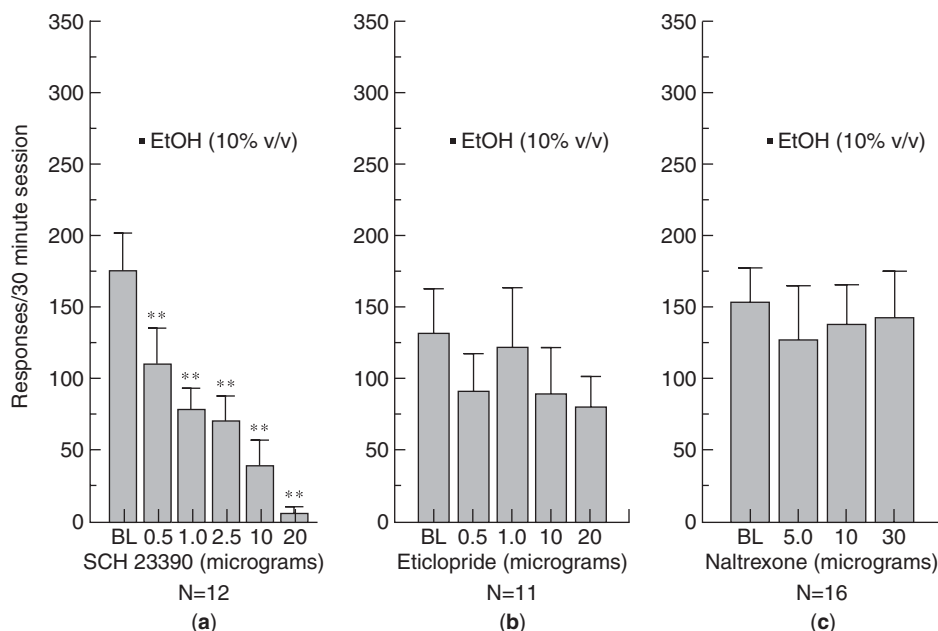

Figure 14.2 (a) Effects of SCH 23390 (0.5–20 µg) following bilateral injection in bed nucleus of stria terminalis (BST) on responding maintained by EtOH (10% v/v). Data are shown as mean \pm SEM. (**) $p \leq 0.01$ SCH 23390 vs. baseline (noninfusion and saline infusion controls). (b) Effects of eticlopride (0.5–20 µg) following bilateral injection in BST on responding maintained by EtOH (10% v/v). Data are mean \pm SEM. Adapted from Eiler et al., 2003.

hypothesis. Eiler et al. [42] directly investigated the potential role of DA (in the BST) on EtOH reinforcement using the microinfusion technique. To accomplish this, P rats were bilaterally infused with the D_1 receptor antagonist SCH 23390 or D_2 -like receptor antagonist eticlopride in the dorsolateral BST following training to lever press for EtOH in an operant paradigm. The results were clear-cut. SCH 23390 produced significant dose reductions on responding maintained by alcohol; however, eticlopride and naltrexone were not effective (Fig. 14.2). These data strongly suggest that EtOH reward is mediated by D_1 -like receptors located within the BST. As EtOH consumption at its core is a consumptive, drinking behavior, it is important to determine if the effects of any drug on EtOH are selective or a result of a suppression of drinking behavior in general. To evaluate reinforcer specificity, animals were trained to operantly self-administer sucrose. In contrast to the findings seen with EtOH, the two highest SCH 23390 and eticlopride doses (2.5 and 20.0 µg) significantly reduced sucrose responding; however, naltrexone was not effective. The results of this study were the first to demonstrate that a D_1 DA receptor subtype within the BST plays a significant role in EtOH reinforcement. While the D_1 receptors also appear to have a regulatory role in sucrose reinforcement, the BST appears most sensitive to EtOH reinforcement. In contrast, neither D_2 receptors nor the opioid system plays a role in the regulation of alcohol-rewarding properties in the BST. Similarly, the opioid systems of the BST do not appear significant in mediating the rewarding properties of sweet palatable solutions.

14.5.2 Ventral Pallidum

Increasing evidence implicates the VP as a dopaminoreceptive brain region regulating drug reinforcement [99–101]. More recent studies, however, have evaluated the ventral pallidal DA system in regulating alcohol-motivated behaviors. One of the first studies to investigate the role of the VP in EtOH reward was conducted by Melendez and colleagues [102]. This study evaluated the levels of extracellular DA within the VP following intraperitoneal administrations of EtOH. Two groups of Wistar rats were surgically implanted with bilateral microdialysis probes aimed at either the VP and the globus pallidus (GP) or the NAcc and the dorsal striatum (dSTR). EtOH (0.0–2.25 g/kg) produced a dose-dependent increase in extracellular DA in the VP but not the GP, with increases similar to those seen in the VP observed in both the NAcc and the dSTR following a 2.25-g/kg dose of EtOH (Fig. 14.3).

Melendez et al. [102] concluded that these data indicated that the mesopallidal system is more sensitive to the effects of EtOH than the nigropallidal. These data, together with results of the NAcc/dSTR portion of the study, suggest that the ventral regions of the striatopallidal complex are more sensitive to the effects of EtOH than the dorsal aspect. The sensitivity of these ventral circuits is in agreement with research that indicates this circuitry is important in mediating the rewarding effects of various drugs of abuse, including EtOH. Unfortunately, however, unlike the Carboni et al. study [48], the alcohol doses used in this study are exceptionally high, and it is not clear what their relevance to alcohol reward might be. As a result, these data should be interpreted with caution when making inferences to alcohol-rewarding effects.

Figure 14.3 Time course effect of sterile saline or 15% (v/v) ethanol at doses of 0.75, 1.5, or 2.25 g/kg on extracellular levels of dopamine in VP and GP of Wistar rats. Values are expressed as percentage of baseline values and represent mean \pm SEM. The i.p. administration of saline or 0.75 g/kg failed to significantly alter the extracellular levels of dopamine in either the VP or the GP ($p > 0.05$). (*) $p < 0.05$ as compared to saline (Dunnett's t); (+) $p < 0.05$ as compared to the GP [one-way analysis of variance (ANOVA)]. Adapted from Melendez et al., 2003.

Figure 14.4 Extracellular levels of dopamine in VP of ethanol, saccharin, and water (control) groups expressed as percentage of baseline during anticipation, self-administration, and postadministration periods. Data are means \pm SEM. Baseline dialysate levels of dopamine of ethanol, saccharin, and water groups were not significantly different (1.1 ± 0.1 , 0.93 ± 0.2 , and 0.85 ± 0.1 nM, respectively). (*) $p < 0.05$ compared with values for water; (**) $p < 0.05$ compared with values for water and saccharin with posthoc Tukey b test. Adapted from Melendez et al., 2004.

In 2004, Melendez and colleagues continued examining the role of the DA system within the VP on EtOH reward [56]. Female P rats, implanted with guide cannula into the VP, operantly self-administered EtOH, water, or saccharin during a microdialysis session divided into four discrete periods: habituation, anticipation, self-administration, and postadministration. While self-administration of saccharin or water had no effect on DA levels within the VP, the presentation of EtOH led to a marked increase in DA output in the anticipatory phase as well as increases throughout the self-administration phase, which decreased postadministration (see Fig. 14.4). Together, the data revealed that, as with intraperitoneal (i.p.) administration, self-administration of EtOH also led to significant increases in extracellular DA levels within the VP. These data further suggest a role of the VP in the anticipation of EtOH reward as well.

In their most recent study, Melendez and colleagues [26] assessed the effect of D_1 and D_2 DA receptor blockade within the VP on the intake of EtOH in a limited-access home cage paradigm employing similar extracellular DA measurement methods. P rats were separated into two groups and implanted with either bilateral guide cannula in the VP or a unilateral microdialysis probe aimed at the VP. Rats of the microinfusion group initiated EtOH intake during a 60-min limited-access paradigm following the microinjection of either the D_1 antagonist SCH 23390 or the D_2 antagonist sulpiride. Animals in the microdialysis group were evaluated for increases in extracellular DA levels following the reverse dialysis of either SCH 23390 or sulpiride.

In the limited-access/microinfusion portion of the experiment, only the highest tested dose of sulpiride (2.0 μg) was effective, producing an increase in intake. Interestingly, while only the highest dose of sulpiride (200 μM) led to an increase in extracellular DA with the VP, all tested doses (10–200 μM) of SCH 23390 were effective.

The data from the limited-access portion of this study suggest that D_2 receptors within the VP (that may be located on GABAergic neurons) play an important role in the regulation of EtOH reward. Evidence exists that such neurons exit from the VP and innervate the NAcc [103]. It is possible that the blockade of these receptors disinhibit the NAcc or perhaps other reward loci innervated by GABA neurons originating from within the VP. Data from the microdialysis portion of this study seem to support the hypothesis insofar as the minimal increase in extracellular DA suggests that the D_2 receptors within the VP are not acting as autoreceptors. This further strengthens the theory that the increase in intake following D_2 blockade is accomplished by non-dopaminergic neurons. Unlike the D_2 system, the D_1 receptor system within the VP appears to play only a minimal role in the regulation of EtOH reward. Reverse microdialysis of SCH 23390, however, led to significant increases in DA levels within the VP. This finding seems to imply the DA release within the VP is regulated in large part by a yet-undetermined D_1 receptor-mediated inhibitory feedback loop. These data also suggest that while EtOH is capable of increasing extracellular DA within the VP, such an increase fails to alter EtOH intake.

Recently, our laboratory also evaluated the effects of DA receptor blockade within the VP on the self-administration of EtOH [104]. For this study, P rats were implanted with bilateral guide cannula aimed at the VP and trained to operantly self-administer EtOH. SCH 23390 (1.0–40.0 μg) and the D_2 -like selective receptor antagonist eticlopride (1.0–40.0 μg) were used for DA receptor blockade. The two highest doses of SCH 23390 (10.0, 40.0 μg) resulted in a marked reduction in lever pressing (Fig. 14.5a). These data implicate the D_1 receptor subtype in the mediation of EtOH, a finding that is somewhat contradictory to that seen in the 2005 Melendez study [26]. Similar to D_1 blockade, eticlopride also led to a reduction in EtOH responding when administered in high doses (20.0–40.0 μg) (Fig. 14.5b). However, when the 10.0- μg dose of eticlopride was microinfused into the VP, it produced a 41% increase in EtOH responding similar to the increases observed by Melendez and colleagues [26]. The overall findings from the research detailed above strongly implicate the VP as an important substrate in the regulation of EtOH self-administration. Microdialysis studies clearly demonstrate that EtOH, whether given via either i.p. injection or self-administration, readily increases DA release within the VP in a manner similar to that seen within the NAcc following exposure to EtOH (see [73]).

14.5.2.1 Hypothesized Mechanisms of Dopaminergic Regulation in Ventral Pallidum Regulating Alcohol-Motivated Behaviors. The precise mechanism(s) responsible for the increase in extracellular DA following EtOH are not clear. Several, hypotheses to explain this phenomenon have been proposed. Melendez et al. [102] suggested that the increased levels of DA within the VP may be higher than those of the GP due to differential sensitivity of the origins of the DA neurons that innervate them. In fact, the DA neurons within the VTA (which contains the cell bodies of the VP DA neurons) have been shown to be five times more sensitive to the effects of EtOH than

Figure 14.5 (a) Effects of SCH 23390 (1.0–40.0 μg) following bilateral injection in VP on responding maintained by EtOH (10% v/v). Data shown as mean ± SEM. (**) $p \leq 0.01$ SCH 23390 vs. baseline (noninfusion and saline infusion controls). (b) Effects of eticlopride (5.0–60.0 μg) following bilateral injection in VP on responding maintained by EtOH (10% v/v). Data shown as mean ± SEM. Adapted from Foster et al., 2002.

those found in the substantia nigra (SN), which innervates the GP [105]. The sensitivity of these neurons may ultimately be the result of GABAergic inhibition which is higher in the SN. It is also proposed that the differential sensitivity may be due to effects EtOH may have in the terminal fields, that is, that innervation from the striatum may affect the release of DA within the VP and GP. The majority of the striatopallidal neurons are GABAergic, and EtOH may act upon these neurons to regulate DA release. Blockade of both GABA_A and GABA_B receptors within the VP

results in increases in extracellular DA within the VP [106]. Further, June and colleagues [19, 37] have previously established a role of GABA_A receptors within the VP in the mediation of EtOH reward. It is also possible that a combination of these two factors could regulate EtOH-related VP DA increases.

The increases in EtOH intake observed by Melendez et al. [26] following D₂ blockade within the VP are compatible with the results seen in other studies involving the self-administration of EtOH [65], amphetamine [107], and cocaine [108]. It is hypothesized that the increase in responding observed is compensatory. Since blockade of the D₂ system may lower the reward efficacy of EtOH, in response the animals self-administer at higher rates in order to compensate for the reduced reinforcement. This hypothesis may be true for a partial blockade produced by lower doses of a D₂ antagonist; however, higher doses lead not to an increase in self-administration but to a decrease. It is possible that as more D₂ receptors are occupied, the reward value of self-administered EtOH reduces even further. While a partial blockade may result in compensatory increases in responding, a more complete blockade may produce such a robust reduction in reward value that the animals no longer possess the necessary motivation to self-administer the drug. As a potential mechanism, Melendez et al. [26] suggest that the D₂ receptors of the VP may reside presynaptically on efferent GABA_A neurons. However, the neuromechanisms regulating these effects are not clearly understood.

Effects on EtOH self-administration produced by the D₁ antagonist SCH 23390 have led to contradictory findings. For example, Melendez [26] reported that while SCH 23390 produced a robust increase in extracellular DA levels within the VP, it had no effect on EtOH intake. However, the study conducted by Foster et al. [104] found that SCH 23390 produced profound reductions in EtOH responding. Melendez suggests that while D₁ blockade does produce profound elevations in DA release within the VP, these increases are not sufficient to influence EtOH drinking behavior. Similar increases within the NAcc also produce no change in EtOH intake [109]. While the DA increase seen following the doses administered in the Melendez study may be insufficient to influence EtOH self-administration, it may be possible that the higher doses used in the Foster study could produce DA levels within the VP that are elevated so that they begin to substitute for the EtOH, thus reducing responding. It is also important to note that the cellular localization of the D₁ receptors within the VP has yet to be determined. It is therefore possible that at higher doses a D₁ antagonist could activate or inhibit pathways that result in the reduction of EtOH reward through a variety of means while still producing increases in extracellular DA within the VP.

Research indicates that the mediation of EtOH reward clearly involves the DA system within the VP. Not only is EtOH capable of producing increases in extracellular DA release within the VP, it also produces anticipatory effects within the VP. Furthermore, both D₁ and D₂ DA receptor subtypes within the VP appear to regulate the reinforcing properties of EtOH, with the D₁ receptors producing a decrease in EtOH self-administration while the D₂ receptors produce biphasic effects with low doses leading to increases and higher doses nearly abolishing EtOH self-administration. Together, the studies presented above suggest that both the D₁ and D₂ receptor subtypes are implicated in the regulation of EtOH self-administration; however, it is clear that while their regulatory control within the VP may be overlapping, there are distinct regulators within the VP which differentiate the two receptors.

14.5.3 Lateral Hypothalamus

The LH, like other reward substrates, receives dopaminergic innervation directly from DA cell bodies located within the VTA as part of the mesencephalic pathway [86, 110, 111]. The LH also contains a number of DA receptors with a higher ratio of D₂ to D₁ receptors [112]. Historically, the DA system within the LH has been implicated in the inhibitory control of both food and water intake [84, 85, 113, 114] as well as inhibiting the locomotor processes associated with the procurement of food and water [115]. This tonic inhibition can be easily removed by local administration of the selective D₂-like antagonist sulpiride, leading to increases in feeding and drinking as well as psychomotor activation [114–116]. The increase in these behaviors, particularly the psychomotor activation, suggests that the LH is in some way involved in mediating the rewarding aspects of eating and drinking along with the initiation of consumptive behaviors that precede intake, as there is often a link sited between the increase in locomotor activity and drug reinforcement [117].

Reward is often associated with the increased release of DA, particularly in brain regions associated with the regulation of the reinforcing properties of various drugs of abuse. Thus, any area that may mediate release of DA into reward areas such as the NAcc may also play a role in the regulation of drug reinforcement. The LH may be one such area. Early studies revealed that electrical stimulation of the LH leads to increased levels of DA and its metabolites within the NAcc [83]. To further investigate the LH's control of DA release within the NAcc, Parada and colleagues [118] examined the effects the D₂ antagonist sulpiride on the DA release within the NAcc. This study found that sulpiride injected directly into the LH led to a dose-dependent increase in DA release within the NAcc at the highest tested dose (Fig. 14.6). Moreover, this study demonstrated that the Sprague–Dawley rats used would lever press in an operant paradigm for direct infusion of sulpiride into the LH, demonstrating a strong link between increased DA release with the NAcc and the reward value of the D₂ antagonist sulpiride (Fig. 14.7). While the data above suggest that the LH is a prime candidate for a DA-mediated reward locus, research into its role in drug reward has been very limited.

June and his colleagues have examined the role of DA within the LH on the regulation of EtOH reward [119]. In this study, the effects of DA blockade using the D₁ antagonist SCH 23390 and the D₂-like receptor antagonist eticlopride were evaluated following bilateral infusion into the LH of P rats. Reinforcer specificity was determined by evaluation of the antagonist on sucrose-motivated responding. Neuroanatomical specificity in modulating alcohol- and sucrose-motivated behaviors was examined following bilateral injections of both SCH 23390 and eticlopride into the ventral thalamus. Figure 14.8b shows that eticlopride (1–40.0 µg) produced both a dose-related and profound reduction on responding maintained by alcohol. In contrast, Figure 14.8a shows that SCH 23390, the highly selective D₁ antagonist, did not alter alcohol responding (not shown are doses as high as 60 µg). Neither antagonist altered sucrose-maintained responding. Hence, eticlopride produces both reinforcer and neuroanatomical specificity in reducing alcohol drinking behaviors.

14.5.3.1 D₂ Dopaminergic Regulation of Alcohol-Motivated Behaviors in LH: Hypothesized Mechanisms. The above findings provide compelling data suggesting that blockade of D₂ receptors within the LH leads to a profound reduction in the

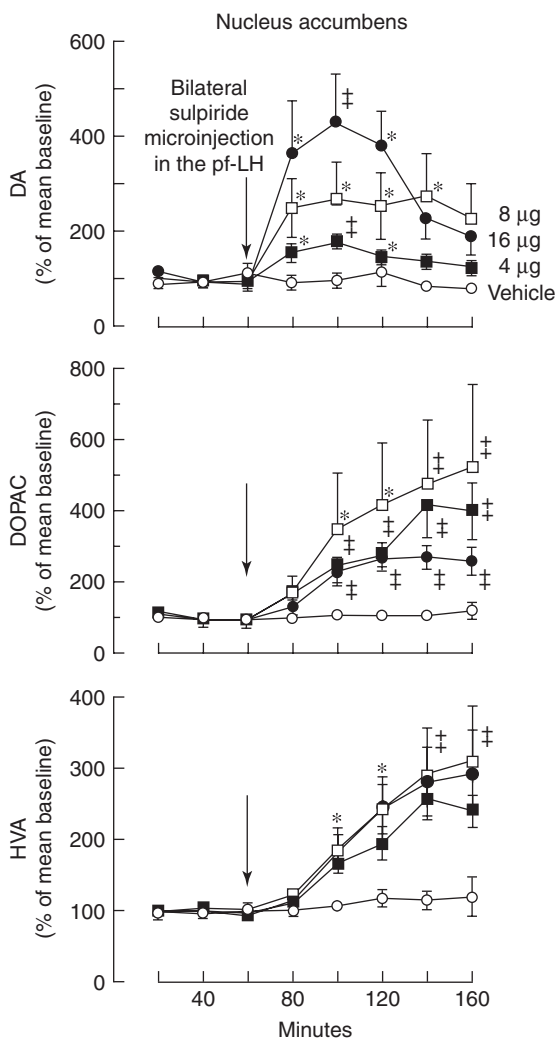

Figure 14.6 Sulpiride injected bilaterally in the prefrontal lateral hypothalamus (pf-LH) increases extracellular DA in NAcc. Curves show extracellular levels of DA (top graph), dihydroxyphenylacetic acid (DOPAC, middle graph), and HVA (bottom graph) in the right NAcc of rats receiving bilateral pf-LH microinjections of sulpiride (filled squares, 4 µg/0.3 µL; open squares, 8 µg/0.3 µL; filled circles, 16 µg/0.3 µL; open circles, 0.3 µL of vehicle). Arrows mark the time of the injection. Symbols indicate statistically significant differences between a data point and its corresponding preinjection level (* $p < 0.01$; †, $p < 0.001$). Data represent the mean \pm SE for four different animals at each dose. Adapted from Parada et al., 1995.

reward efficacy of EtOH. However, this decrease in reward value was not seen for sucrose following either D_1 or D_2 blockade, suggesting that its reward value may be mediated either by a different neurotransmitter system within the LH or in another substrate altogether. As seen with sucrose, D_1 blockade within the LH also failed to reduce responding for the EtOH solution.

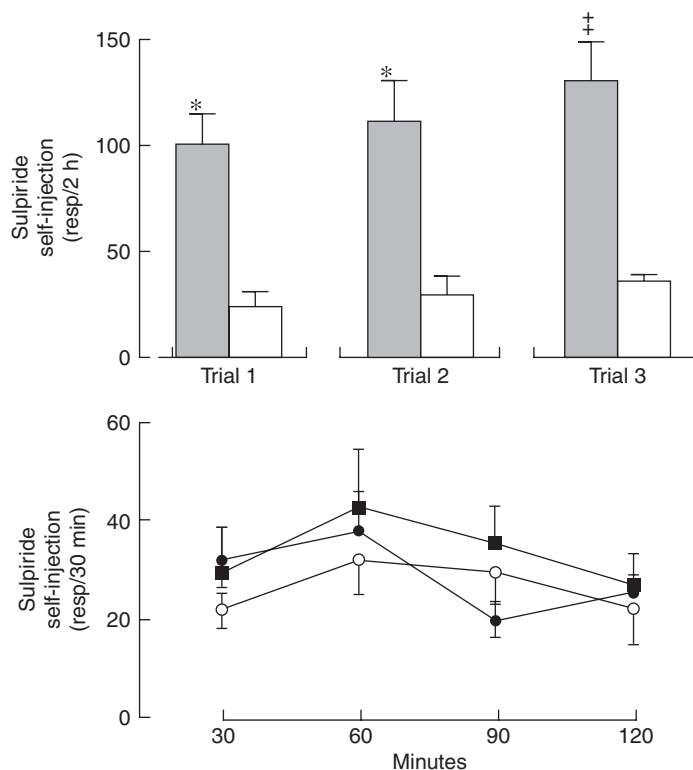

Figure 14.7 Intrahypothalamic self-administration of sulpiride in five rats during sessions (trials) on three different days. Each press of the active lever delivered a 2-s injection of 21.5 ± 1.28 nL of 10 ng/nL sulpiride. Presses on the blank lever were recorded but they did not have any contingent value. Top graph: response frequency on the active lever (filled columns) and the blank lever (open columns) during each session. Symbols indicate significant differences between responses on the active and blank levers (*) $p < 0.01$; ‡, $p < 0.001$). Bottom graph: response frequency on the active lever was consistent in all four 30-min periods during the first (open circles), second (filled circles), and third (filled squares) trials on three different days. Adapted from Parada et al., 1995.

As demonstrated above, the D_1 system produced no change in either EtOH or sucrose responding; however, the absence of effects seen with SCH 23390 may be readily explained. Thus, the LH possesses only a limited number of D_1 receptors [112]. These low numbers may render the D_1 system within the LH ineffective in mediating reinforcement resulting in minimal change in EtOH and sucrose response rates.

While the effects of the D_2 blockade on EtOH self-administration are quite clear, determining the mechanism responsible for this reduction is far more difficult. Nonetheless, plausible explanations are possible. One possible explanation may center around the increased release of accumbal DA previously observed following LH D_2 blockade. As discussed above, D_2 blockade within the LH has been shown to result in increased DA release within the NAcc. This would suggest that such a blockade might in fact increase the reward value of EtOH insofar as increases in

Figure 14.8 (a) Effects of SCH 23390 (1.0 and 20.0 µg) following bilateral injection in the LH on responding maintained by EtOH (10% v/v). Data are shown as mean ± SEM (***) $p < 0.01$ SCH 23390 vs. baseline (noninfusion and saline infusion controls). (b) Effects of eticlopride (2.5–20.0 µg) following bilateral injection in the LH on responding maintained by EtOH (10% v/v). Data shown as mean ± SEM. Adapted from Goergen et al., 2003.

accumbal DA often denote reward efficacy. However, this assumes that the increase in accumbal DA release seen following EtOH self-administration (see [73]) produces an additive effect with the increase in DA release seen with D_2 blockade within the LH [118]. Alternatively, the increased DA release in the NAcc following D_2 blockade within the LH may serve to substitute for the DA release typically seen following EtOH administration. Such a substitution would, in theory, lower the reward value of EtOH resulting in a lowered desire to “work” for the EtOH. This hypothesis, however, fails to explain the effect seen on sucrose consumption. An increase in sucrose responding is expected, because D_2 blockade increases drinking behavior

[114–116]. However, no appreciable change in responding is seen following LH D_2 blockade. It is possible that while the D_2 blockade leads to increased consumptive behaviors, it may not be sufficient to increase the motivation necessary to respond for the sucrose in a self-administration paradigm.

While further research is necessary to identify the mechanisms by which the D_2 antagonist eticlopride reduces EtOH self-administration, it is clear that the D_2 system within the LH strongly regulates the reinforcing properties of EtOH. Indeed, the LH's strong ties to the regulation of the consumptive behaviors of feeding and drinking make it an important site for further EtOH research as alcohol intake can be classified as a drinking behavior. In addition, its clear ability to modulate DA levels within the NAcc may further establish the LH as an important dopaminergic substrate regulating not only EtOH reward but also the rewarding properties of various drugs of abuse.

14.5.4 Summary

The neurocircuitry and mechanisms that mediate the propensity to consume EtOH are complex. The focus in EtOH research thus far has clearly been on the DA system of the mesolimbic pathway, particularly the interaction of the NAcc and the VTA. However, evidence has begun to emerge that may shift the focus from the DA system within the NAcc to other substrates that are innervated by DA neurons arising from the VTA DA cell bodies. The purpose of this section has been to describe novel DA substrates that may be involved in the regulation of EtOH reward. To this end, studies involving three DA-innervated substrates—the BST, VP, and LH—were described in the hopes that future research may involve not only the investigation of the NAcc in EtOH reward but also other dopaminergic brain loci.

Increases in extracellular DA within the NAcc have been observed in a number of studies following the delivery of EtOH through various routes of administration (see [51]). In fact, it has been generally accepted that an increase in extracellular DA following administration is one way to classify a drug as reinforcing. As demonstrated in the studies reviewed above, EtOH administration is capable of inducing elevated extracellular DA levels in the BST and VP. Intraperitoneally administered EtOH at doses that induce euphoric effects has been shown to increase DA release within the BST [48]. A number of studies of DA release in the VP have been conducted by Melendez and colleagues demonstrating that extracellular DA levels increase within the VP following not only i.p. administration but also self-administration in both operant and limited-access paradigms [26, 56, 102]. This group also observed an increase in DA levels following the reverse microdialysis of the D_1 antagonist SCH [26]. While there are no reports of an increase in extracellular DA within the LH, D_2 blockade within the LH is sufficient to produce increases in NAcc DA levels [118]. Although this is not direct evidence that EtOH can influence DA within the LH, it does show that the LH can effectively modulate DA within a substrate shown to regulate EtOH reward.

While the evaluation of extracellular DA is important in establishing a role of a DA system within a substrate in EtOH reinforcement, it does not provide evidence that the substrate can regulate EtOH reinforcement. One method of determining a more direct regulatory role of DA within a brain structure is via use of DA agonists

or antagonists. Using these selective DA agents, it was found that the blockade of the D₁ system within the BST led to robust reductions in EtOH responding with no effect seen with D₂ blockade; therefore, EtOH reinforcement is regulated by D₁ receptor subtypes within the BST [42]. Melendez administered D₁ and D₂ antagonists within the VP via reverse microdialysis and found that the D₁ system had no effect on EtOH reward while blockade of the D₂ system produced increases in intake, suggesting that EtOH reward is mediated by the D₂ receptors within the VP [26]. Different results were seen following microinjection of D₁ and D₂ antagonists into the VP. Using an operant self-administration paradigm, Foster et al. [104] found increases in intake similar to those observed by Melendez, but only at low doses. In contrast, high doses of the D₂ antagonist eticlopride produced robust reductions in EtOH responding. Similar reductions were also observed following the administration of high doses of the D₁ antagonist SCH 23390. These data suggest that EtOH reinforcement may be regulated in a biphasic fashion by D₂ receptors within the VP along with D₁ mediation of reward [104]. The D₂ system also seems to be the regulator of DA reward within the LH. Blockade of the D₂ receptors within the LH led to robust reductions in EtOH responding in a self-administration paradigm [119]. These data demonstrate that while the DA systems in various substrates may mediate EtOH reward efficacy, they do so by the use of differential activation of the D₁ and/or D₂ receptor subtypes.

While the studies discussed in this section detail research on DA's control of EtOH reinforcement in novel substrates, it is important not to discount possible interactions between the DA systems of these brain regions and other neurotransmitter systems. In fact, other studies demonstrate that GABAergic systems can lead to modulation of the effects produced by DA antagonism in both the BST and VP (Eiler et al., unpublished; see also [104]). It is thought that the mechanism of action driving DA regulation of EtOH reinforcement is not simply altering/modulating DA release within key dopaminergic loci but is the result of complex interactions between DA and GABA pathways. Clearly, DA interacts with other neuronal systems such as neuropeptides and glutamate [52]. In short, the elucidation of novel DA substrates regulating EtOH reward provides investigators with new challenges in determining the neurocircuitry that mediates EtOH reinforcement.

In summary, evaluating only DA neuroanatomical substrates and systems within the mesolimbic and extended amygdala pathways may limit our understanding of how the complex interactions within these pathways function to control EtOH-reinforced behaviors. Moreover, it is now clear from the work of both Rassnick et al. [78] and Myers and Quarfordt [120] that removal of the mesolimbic DA system does not alter established EtOH self-administration [121]. As such, other neurotransmitters may be differentially involved in various aspects of the reinforcement process. Since it is likely that EtOH-motivated behaviors are mediated by multiple neurochemical systems, the fundamental neuropharmacological information provided by the study of overlapping neuronal systems is essential to understanding the neural processes that regulate EtOH self-administration. In this review, we describe recent studies evaluating the significance of GABA_A receptors in EtOH-seeking behaviors. These studies have advanced our understanding of the neural mechanisms regulating alcohol drinking. Exploitation of compounds selective for specific GABA_A receptor-containing subunits has now led to novel prototype ligands that may have clinical utility in the treatment of alcohol dependence.

14.6 MOLECULAR BIOLOGY OF THE GABA_A BDZ RECEPTOR

GABA is the most abundant inhibitory neurotransmitter present in the mammalian brain. Although there are, to date, at least three unique classes of GABA receptors, the majority of neurobehavioral research on alcoholism has centered on GABA_A receptors, referred to as the GABA_A benzodiazepine (BDZ) receptor complex. This complex has been characterized as a pentameric structure comprised of at least 16 identifiable subunits (α_{1-6} , β_{1-4} , γ_{1-3} , δ , ρ , and ϵ) in the mammalian CNS [122]. Identifying the various receptor subunits and their function has become increasingly important to gain an understanding of the neurobiological base of alcoholism and treatment target identification. The GABA “system” has been suggested to be the best candidate for a “single” neurotransmitter in regulating the neurobehavioral effects of alcohol [123–125]. Specifically, these effects include alcohol-motivated behaviors [1, 18, 19] as well as the motor-impairing, sedative [28, 124] and anxiolytic [28, 126, 127] properties of alcohol. Here, the neuropharmacological, neuroanatomical, and molecular biological underpinnings of alcohol-motivated behaviors/self-administration are reviewed. The role of the GABA system in other neurobehavioral actions of alcohol has been reviewed elsewhere [124, 128].

14.6.1 Commonalities of Alcohol and Modulators of the GABA_A BDZ Systems

EtOH shares many common behavioral properties with BDZs and barbiturates (e.g., sedation, ataxia, anxiolysis). Similar to BDZs and barbiturates, EtOH potentiates GABA-stimulated Cl[−] flux (for a review see [129]). Hence, it has been postulated that EtOH's action at the level of the GABA-coupled Cl[−] ion channel may underlie many of its behavioral properties [130–132]. The effects of EtOH are thought to be selective for GABA_A receptors since they are antagonized by negative modulators of GABAergic activity such as BDZ inverse agonists, the GABA_A receptor antagonist bicuculline, and the Cl[−] channel blocker picrotoxin [133]. Further, manipulations of central GABAergic activity alters many of the behavioral and physiological effects of EtOH [126, 132, 134, 135], including reinforcement ([78, 136]; also, for a recent review see [19]). Hence, the allosteric modulatory properties of the GABA_A BDZ receptor complex, which allows for neuropharmacological enhancement and reduction of GABAergic function, provides a vehicle to exploit the GABA system to evaluate its significance in regulating alcohol drinking behaviors. Indeed, this neurobehavioral strategy was first demonstrated in the highly cited paper by Suzdak et al. [132] using the partial BDZ inverse agonist RO15-4513. In addition, this neuropharmacological exploitation of the GABA system has been catalyzed by the rapid advances in molecular biology that have resulted in the cloning of key GABA_A receptor subunits [137–140], resulting in knowledge of the heterogeneity and distribution of these receptors [141–143]. For example, substantial research has shown that both the affinities and efficacies of drugs acting at this family of ligand-gated ion channels appear to be defined by subunit composition [137, 144, 145].

The impact of subunit composition on drug action at both recombinant and wild-type GABA_A receptors is best characterized by the chemically diverse class of compounds referred to as the BDZ receptor site ligands [137, 140]. Studies in recombinant GABA_A receptors have shown that the α subunit is the primary determinant of ligand affinity, while the γ subunit affects affinity of a more

circumscribed class of compounds, but can dramatically alter ligand efficacy [139, 144–146]. Hence, knowledge of both the affinity and efficacy of BDZ site ligands has permitted the design/development of pharmacological probes to manipulate the GABA BDZ receptor complex to determine the neuromechanism(s) of action of alcohol drinking behaviors. In addition, the development of these ligands has also provided the opportunity to explore and make inferences about the role GABA systems may play in regulating alcohol drinking behaviors (see below).

14.6.2 GABA_A BDZ Modulation of EtOH Self-Administration: Studies Using Systematic Application of Probes

Substantial evidence now suggests that GABA_A receptor-mediated neurotransmission within the mesocorticolimbic system plays a prominent role in regulating EtOH-motivated behaviors (for a recent review see [19]). Early work demonstrated that GABAmimetics decreased voluntary EtOH intake [147–149], while agents like pentobarbital [150] and diazepam [151] were observed to increase EtOH consumption. In addition, subsequent studies by Amit and his colleagues [152, 153] demonstrated that systemically administered tetrahydroisoxazopyridino (THIP), a GABA agonist, enhances EtOH intake during a 24-h interval. Bretazenil, a partial agonist, has also been observed to increase EtOH intake in AA alcohol-preferring rats [154]. Studies evaluating the role of increased GABA transmission on EtOH-motivated behaviors in the operant chamber, however, have generally resulted in equivocal results on the one hand or no effects on the other. Specifically, Samson and Grant [33], using a concurrent schedule procedure, demonstrated that chlordiazepoxide (CDZ) generally reduced EtOH responding and intake. Rassnick and her colleagues [78] were not able to demonstrate any reliable increases or decreases in EtOH with P and alcohol-non preferring (NP) rats following CDZ (2.5–10 mg/kg) administration. However, using a modified sucrose-fading procedure, Petry [155] demonstrated that low CDZ doses (1–4 mg/kg) significantly and selectively increased EtOH responding, while higher doses (10–20 mg) decreased EtOH responding. In contrast to the equivocal findings evaluating the role of increasing GABA transmission on EtOH self-administration, systemic administration of BDZ inverse agonists [e.g., RO15-4513, FG 7142, methyl-6,7-dimethoxy-4-ethyl-beta-carboline-3-carboxylate (DMCM)] have been consistently reported to reduce EtOH consumption under a variety of self-administration paradigms (for reviews see [156, 157]). For example, RO15-4513 has generally been reported to dose dependently and selectively suppress EtOH intake [7, 156, 158] and responding [78, 159, 160].

Because of the demonstrated selectivity of RO15-4513 in reducing alcohol intake, subsequent work focused on RO19-4603, a related BDZ inverse agonist with a unique pharmacological profile [20, 161]. Unlike RO15-4513, RO19-4603 is an imidazothienodiazepine derivative of RO15-3505 (samazenil), with exceptionally high binding affinity ($K_i = 0.2$ nM) [162]. Figures 14.9a and b show data for P rats ($N = 10$) which initiated EtOH-reinforced responding using a modification of the sucrose-fading procedure under a concurrent FR4 operant schedule for days 1 and 2. RO19-4603 (0.0045–0.3 mg/kg, i.p.) was given 5 min prior to day 1 only. RO19-4603 reduced response-contingent EtOH intake by as much as 97% of controls on day 1, and responding continued to be reduced 24 h post-drug administration by as much as 85% of controls on day 2. CGS 8216, a specific BDZ antagonist, significantly attenuated the RO19-4603 reduction on day 1 and completely reversed the effects on

Figure 14.9 Dose-response and time course of i.p. administration of RO19-4603 (0.0045, 0.009, 0.0187, 0.0375, 0.075, 0.15, 0.3 mg/kg) and vehicle given acutely on day 1 (a) and 24 h post-drug administration day 2 (b) on EtOH-reinforced (10% v/v) responding and saccharin-reinforced (0.05% g/v) responding. The RO19-4603 injections were given 5 min prior to test session on day 1 only. RO19-4603 suppressed EtOH-reinforced responding, while the 0.0045-, 0.009-, and 0.0187-mg/kg doses elevated saccharin-reinforced responding on day 1. Day 2 showed suppression of EtOH-reinforced responding and parallel increases of saccharin-reinforced responding for each of the seven doses of RO19-4603. (*) $p < 0.05$ and (**) $p < 0.01$ vs. control vehicle values by ANOVA and post hoc Newman-Keuls test at a corresponding day. Adapted from June et al., 1998.

day 2. Thus, the effects of RO19-4603 may be mediated at the BDZ binding site of the GABA_A BDZ receptor complex. The degree of selectivity of RO19-4603 on EtOH responding, however, could not adequately be determined from this study, primarily because EtOH and saccharin responding were not equated at basal levels; however, analyses of the cumulative records revealed that RO19-4603 produced a dose-dependent decrease in the slope of the cumulative record for EtOH responding while concomitantly producing a dose-dependent increase in the slope for saccharin responding (see Fig. 14.10). Thus, the actions of RO19-4603 “appear” to be mediated via recognition sites at GABA_A BDZ receptors which regulate EtOH reinforcement, and not mechanisms regulating general ingestive behaviors.

In the evaluation of BDZ ligands for their effectiveness to attenuate EtOH responding, June and colleagues have determined if qualitative (i.e., imidazobenzodiazepine-selective) and quantitative (affinity for diazepam insensitive (DI) sites; see [144, 162a]) differences exist in a compound's ability to decrease EtOH responding (see [28]). RU 34000 is a novel imidazopyrimidine inverse agonist with relatively low affinity at BDZ receptors ($K_i \sim 0.98 \mu\text{M}$) [163] and little affinity at DI sites [164]. Pharmacokinetic analyses, however, have shown that this low affinity is compensated for by the high drug levels of RU 34000 in the brain ($10 \mu\text{g/mL}$) [165]. RU 34000 was an effective antagonist of EtOH responding via the i.p. route. Effects on saccharin responding were seen only with the highest i.p. dose (5 mg/kg). Flumazenil (6 mg/kg , i.p.) completely attenuated the RU 34000 reduction of EtOH responding (data not shown), suggesting that the actions of RU 34000 may be mediated at central BDZ sites. The data with RU 34000 allow several interpretations: First, in addition to the affinity of BDZ ligands at active CNS sites, their bioavailability is an important factor in their capacity to function as EtOH antagonists; second, the capacity of BDZ ligands to function as effective EtOH antagonists is not specific to imidazobenzodiazepines; and third, it is likely that the DI GABA_A receptors (i.e., those receptors either an α_4 or α_6 subunit) may not be a critical factor regulating EtOH-maintained responding.

Work with several BDZ antagonists has also revealed some interesting findings using operant methodology [166]. Figure 14.11 shows that unlike the prototypic BDZ antagonist RO15-1788 (flumazenil), the pyrazoloquinoline CGS 8216 ($1\text{--}20 \text{ mg}$) and the β -carboline antagonist ZK 93426 ($5\text{--}50 \text{ mg/kg}$) produce marked suppressant effects on EtOH responding [166, 167]. Further, 24 h post-drug administration, nonsignificant effects were seen with the lower doses and significant effects with some of the higher doses of these agents [see 161, 168]. It should be noted that, like flumazenil, both ZK 93426 and CGS 8216 are well tolerated in human subjects [169, 170], and it is possible that these agents may have some capacity to reduce EtOH drinking in humans. The exact mechanism by which BDZ antagonists reduce EtOH drinking is not clear. Mild agonist effects for ZK 93426 have also been reported in vivo in rats [171] and humans [172]. In rats, CGS 8216 produces weak to moderate anxiogenic effects, resembling a weak partial inverse agonist [173]. Moderate to strong agonist effects, however, have been consistently reported in vitro in the *Xenopus* oocyte assay for ZK 93426 [18, 37] (see below). Thus, one possible interpretation of the antagonism of EtOH drinking by ZK 93426 and CGS 8216 is that a “BDZ agonist-like ligand” substitutes for the reinforcing actions of EtOH [78], as has been reported with DA agonists in blocking the reinforcing properties of EtOH (cf. [17]). Nevertheless, because of the potential clinical applications of BDZ antagonists,

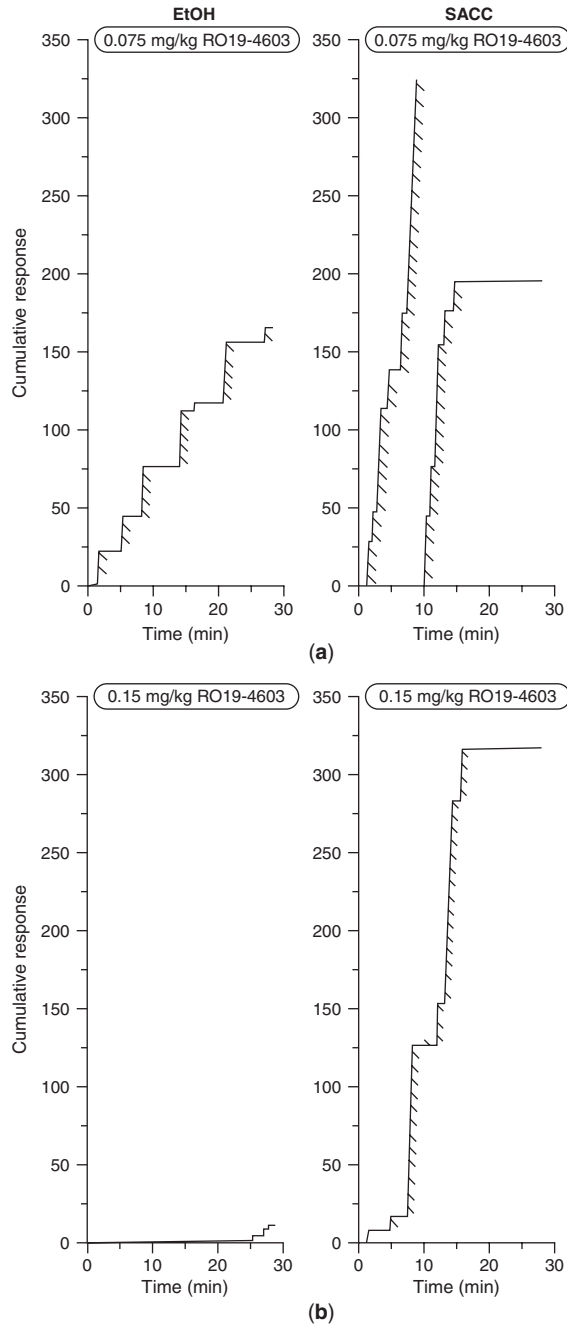

Figure 14.10 Sample cumulative dose-response records for EtOH (10% v/v) and saccharin (0.05% g/v) responding in two additional P rats during a concurrent schedule (FR4–FR4) following 0.075 mg/kg of RO19-4603 (a) (upper panel) or 0.15 mg/kg of RO19-4603 (b) (lower panel). Cross-hatch equals delivery of reinforcer, while the slope of lines indicate response per rate per minute. Adapted from June et al., 1998.

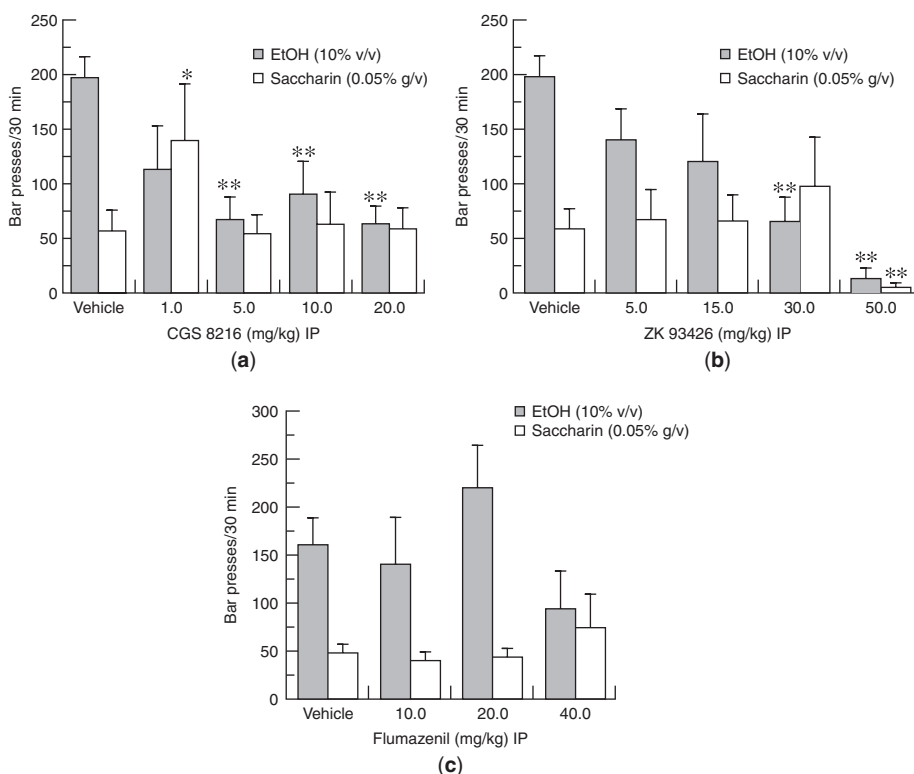

Figure 14.11 (a) Dose–response of i.p. administration of flumazenil in doses of 0 (Tween-80), 10, 20, and 40 mg/kg on responding maintained by EtOH (10% v/v) and saccharin (0.05% g/v) (FR4-FR4). The flumazenil injections were given 20 min before the test sessions ($n = 10$). (b) Dose–response and time course of i.p. administration of CGS 8216 (1, 5, 10, and 20 mg/kg) and vehicle on responding maintained by EtOH (10% v/v) and saccharin (0.05% g/v) (FR4-FR4). The CGS 8216 injections were administered 20 min before the test session. (c) Dose–response and time course of i.p. administration of ZK 93426 (5, 15, 30, and 50 mg/kg) and vehicle on responding maintained by EtOH (10% v/v) and saccharin (0.05% g/v) (FR4-FR4). The ZK 93426 injections were administered 20 min before the test session. (*) $p < 0.05$ and (**) $p < 0.01$ vs. control vehicle values by ANOVA and post hoc Newman–Keuls testing at a corresponding day ($n = 10$). Adapted from June et al., 1998.

additional studies are warranted to further understand the mechanism by which they decrease EtOH reinforcement. Another hypothesis regarding the capacity of BDZ antagonists to attenuate alcohol intake is that because they “generally” do not result in a functional increase or decrease in GABAergic activity, it is possible that their effects on EtOH responding are likely due to their binding at various GABA_A-containing receptor subunits [19, 166].

14.6.2.1 Significance of Systemic Studies. Systemic administration of RO19-4603 produced clear dose-related reductions on EtOH-maintained responding. Compared with other inverse agonists [e.g., RU 34000, Samazenil, ethyl beta-carboline-3 carboxylate (β CCE), RO15-4513], RO19-4603 was considerably more potent, selective, and long lasting in reducing EtOH-maintained responding. Cumulative dose-response profiles

revealed that RO19-4603's actions on EtOH responding appear to be mediated via recognition sites on the GABA_A/BDZ receptor complex which regulate EtOH reinforcement, and not via mechanisms regulating ingestive behaviors in general (see Fig. 14.9). Moreover, the prolonged effects of RO19-4603 on EtOH self-administration was also observed in outbred rats for at least 48 h after a single administration [174], suggesting that these effects are not specific to the P rat line. Attenuation of the RO19-4603-induced suppression on days 1 and 2 by a high-affinity, competitive BDZ antagonist suggests that this effect on EtOH-maintained responding is mediated at the BDZ component of the GABA_A/BDZ receptor complex. Thus, RO19-4603 may be the ideal pharmacological tool to microinject into novel CNS sites to evaluate the role of GABAergic neurotransmission in EtOH reinforcement.

The demonstration that selected BDZ antagonists can blunt the reinforcing properties of EtOH suggests a direct role for the BDZ binding site on the GABA_A BDZ receptor complex in EtOH-seeking behavior. The precise mechanisms by which BDZ antagonists reduce EtOH drinking, however, are not clear, primarily because these studies employed systemic injections. Using the microinjection technique, however, it may be possible to more precisely delineate the neurobiological mechanism(s) in regulating EtOH reinforcement, particularly in a well-characterized model of EtOH-seeking behavior (e.g., P and HAD rats). Finally, because "neutral competitive" BDZ ligands produce few untoward effects in animals and humans ([169, 170] see [166]), they represent excellent pharmacological tools to explore the neurobiology of alcohol reinforcement. A review of the literature on BDZ competitive ligands (see [169, 170]) also shows that neither ZK 93426 nor CGS 8216 produces untoward effects in humans, further supporting the utility of its use in alcohol drinking studies.

14.6.3 Site-Specific Microinjection Studies: Manipulation of GABA_A BDZ Receptor Complex in Modifying EtOH Self-Administration

Little is known about the neurochemical and neuroanatomical substrates via which manipulation of the GABA_A BDZ receptor complex can modify EtOH self-administration within the mesolimbic/mesoaccumbens system. The initial paper to appear in the published literature [55] examined the role of GABA_A receptors in the extended amygdala on EtOH-reinforced responding in outbred rats. As noted previously, the extended amygdala comprises the central nucleus of the amygdala, the bed nucleus of the stria terminalis and the shell of the NAcc, and the subnucleus SI [175]. Animals were trained to initiate EtOH intake using the saccharin-fading procedure. The effects of bilateral microinjections of the competitive GABA_A receptor antagonist SR 95531 were evaluated in three of these brain loci. SR 95531 injected in the bed nucleus of the stria terminalis reduced responding for EtOH with the 8- and 16-ng doses, while only a 16-ng dose produced a significant effect in the shell of the NAcc. However, injections into the bed nucleus of the stria terminalis and the NAcc suppressed both EtOH and water responding at the highest doses during the initial part of the drinking session. Intra-amygdaloid injections did not disrupt the initiation of responding. These findings suggested that the GABA_A receptors in the extended amygdala may be involved in the mediation of some aspects of EtOH reinforcement. Hyttiä and Koob [55] contend the differential sensitivity of the central amygdala, bed nucleus, and shell of the NAcc may result from differences in density

of GABAergic neurons. Indeed, the NAcc contains fewer GABAergic neurons than the bed nucleus of the stria terminalis or the central amygdala [88]. It is important to note, however, that reinforcer specificity could not accurately be determined in that study because rats responded for a (nonpalatable) water solution and responding for the water solution was so low as to confound ready interpretation.

GABAergic manipulations within the mesocorticolimbic DA systems have been investigated primarily with the GABA_A agonist muscimol and the GABA_A antagonist bicuculline. Hodge et al. [176] hypothesized that since local infusions of muscimol into the VTA had been previously shown to increase DA in the NAcc [177], it was possible that such interactions could modulate (directly or indirectly) EtOH-reinforced responding. Hodge et al. [176] evaluated the effects of bilateral microinjections of muscimol (1–30 ng) and bicuculline (1–10 ng) in the NAcc of outbred rats after they were trained under the sucrose-fading procedure. The 10- and 30-ng doses of muscimol significantly decreased EtOH responding. Similarly, the 3- and 10-ng doses of bicuculline also reduced responding. When a dose of bicuculline (1 ng, a dose that had no effect on EtOH given alone) was coadministered with muscimol, it attenuated the muscimol-induced decrease in EtOH responding. Together, these findings suggested that the effects seen with muscimol were mediated by activity at GABA_A receptors and that GABAergic transmission in the NAcc is involved in EtOH reinforcement, possibly via inhibition of DA function [176]. In a subsequent study, these same researchers [178], employing similar methods, evaluated in the VTA the effects of bilateral infusions of higher doses of muscimol (10, 30, and 100 ng) on EtOH (10%, v/v) and sucrose (75%, w/v) responding in separate groups of rats. The results showed that muscimol (10 ng) increased the number of sucrose responses but had no effect on the total number of EtOH responses. However, the 30-ng dose shifted the response pattern of both groups from high initial rates with early termination to slow initial rates with delayed termination, suggesting nonspecific effects. Nevertheless, taken together, these data suggest that muscimol differentially alters EtOH and sucrose responding via GABAergic mechanisms within the VTA, in that EtOH reinforcement is less sensitive to GABAergic manipulation compared with sucrose responding. These investigators employed a very high sucrose concentration in the VTA study; hence, the efficacy of the alcohol and sucrose is very difficult to equate, particularly in outbred rats (see [4]).

To further investigate the role of the GABA system in the mesoaccumbens system, June and colleagues [161, 179] conducted several studies with RO19-4603. The main objectives of these studies were to evaluate, first, its prolonged time course of alcohol reduction in the operant chamber and, second, the substrate by which it exerted its effects. Figure 14.12 shows data for P rats trained to bar press for EtOH under the saccharin-fading procedure following unilateral intra-accumbens infusions of RO19-4603 (2–100 ng). Similar to the systemic study (see above), infusions were performed *only* on day 1. Microinjections of RO19-4603 (20 and 100 ng) into the NAcc suppressed EtOH responding on day 1 by as much as 53% of control, and responding continued to be suppressed on day 2, with the 100-ng dose reducing responding to 73% of control. Thus, similar to systemic injection, prolonged effects were observed with RO19-4603. Cason et al. [180] examined outbred Wistar rats following unilateral injections of *tert*-butyl-8-acetylene-5,6-dihydro-5-methyl-6-oxo-4*H*-imidazo-[1,5*a*] [1,4]-benzodiazepine-3 carboxylate (TG) on day 1 and 24 h post-drug administration. Note that RO19-4603 is also a *t*-butyl ligand; however, TG

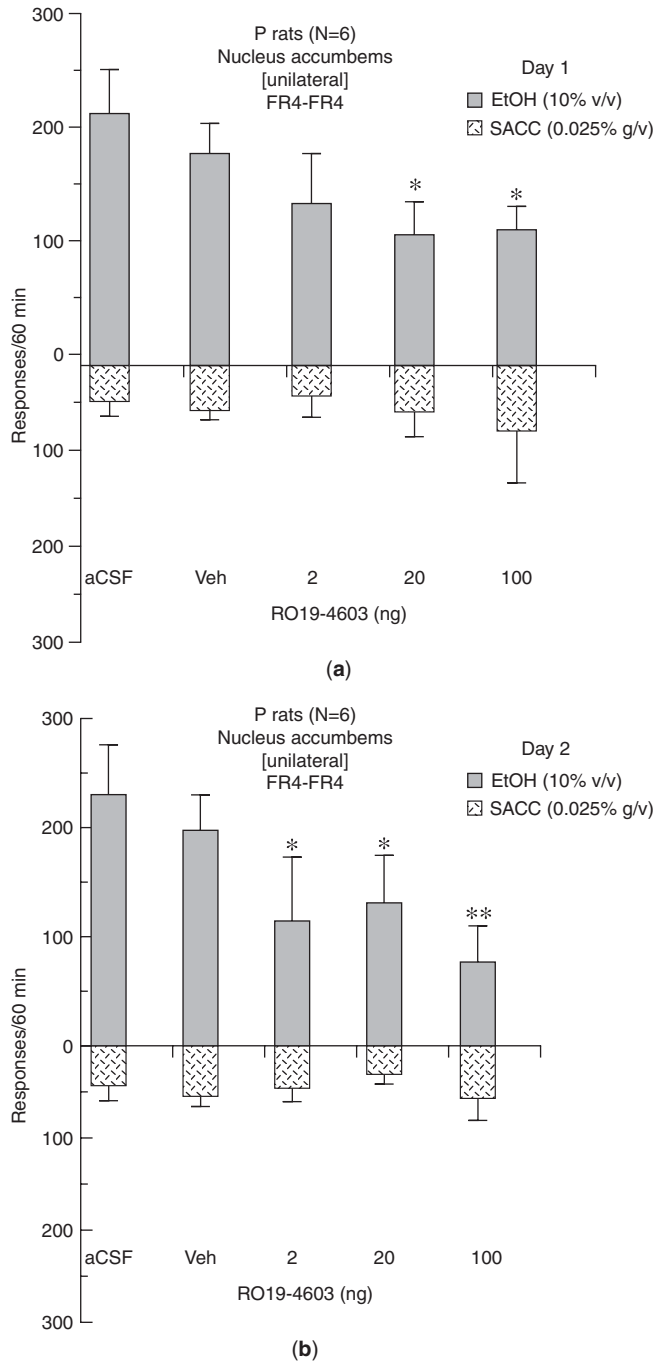

Figure 14.12 Time course of intra-accumbens infusion of RO19-4603 [aCSF (0.0), 2, 20, 100 ng] given acutely on day 1 (a) and 24 h post-drug administration day 2 (b) on EtOH (10% v/v) and saccharin-reinforced (0.05% g/v) responding. (*) $p < 0.05$ and (**) $p < 0.01$ vs. aCSF and vehicle control condition values by ANOVA and post hoc Newman-Keuls test at a corresponding day. Adapted from June et al., 1998.

differs from RO19-4603 in that it is a *t*-butyl acetylene. TG was synthesized by Cook and colleagues for comparison with RO19-403 in our EtOH-maintained responding studies. Following unilateral infusions of TG into the accumbens, the lower dose of TG (200 ng) selectively reduced responding on day 1, but the higher dose (500 ng) nonselectively reduced both EtOH and saccharin responding. On day 2 (24 h postdrug), TG continued to selectively reduce EtOH responding without altering saccharin-maintained responding. The 24-h post-drug administration results with TG replicate the long time course effects on EtOH-maintained responding seen with RO19-4603 in P rats. It should be noted that both EtOH and saccharin response rates were similar at basal levels in the Wistar rats. However, unlike the RO19-4603 study, rate dependency effects cannot adequately explain the efficacy of TG as an EtOH antagonist [180]. These data suggest [168] that the pharmacokinetics of such ligands may be important in their long duration of action since typical ester-derived agents (e.g., RO15-4513, RY 008) are short-lived *in vivo* since they are readily deactivated by esterase enzymes. This is not the case with the *t*-butyl analogs since they cannot readily be deactivated by such enzymes. Consequently, *t*-butyl agents may exhibit a more prolonged duration of action *in vivo* [181]. These data are interesting insofar as modification of such agents to eliminate their negative efficacy could result in prototypes which may reduce alcohol consumption over a long time course.

P rats were administered bilateral microinjections into the VTA using the inverse agonist RU 34000. The purpose of this experiment was to determine if a non-imidazobenzodiazepine inverse agonist could also attenuate EtOH responding via the GABAergic DA reward circuitry. Clear, dose-dependent suppressant effects were observed on EtOH responding following RU 34000 (50–200 ng) in the absence of any effects on saccharin responding. Similar to the systemic studies (see [168]), no effects of RU 34000 were observed on day 2. These data suggest that RU 34000 may be a useful tool to further investigate the effects of the GABA_A BDZ systems in mediating EtOH reward in the VTA and that an imidazobenzodiazepine structure may not be critical to observe reduction on alcohol intake within the mesolimbic circuitry.

These findings allow for several interpretations: (1) GABAergic transmission through GABA_A BDZ receptors contributes to the mediation of EtOH reinforcement in the mesoaccumbens limbic circuitry; (2) in rodents, high voluntary EtOH consumption does not appear to be linked to the reinforcing properties of EtOH in a manner that would permit GABAmimetics or BDZ agonists to substitute for EtOH; and (3) the specific neuroanatomical circuits participating in GABAergic modulation of EtOH self-administration cannot be determined from systemic studies, primarily because of the widespread distribution of GABA_A receptors located in the CNS. Hence, additional microinjection studies are needed to further identify central GABAergic mediation of EtOH reward sites.

14.6.4 Studies Supporting Hypothesis That GABA–DA Interactions Regulate Alcohol-Motivated Behaviors: GABAergic Modulation of DA Function

The VTA receives GABAergic inputs from the medial prefrontal cortex (MPC), VP, and NAcc [182]. In addition, it is well established that substantial GABAergic interneurons exist within the VTA [64]. These GABAergic projections appear to modulate activity of DAergic neurons with cell bodies localized within the VTA. Ikemoto et al. [183] demonstrated that microinjections of picrotoxin (a nonselective

GABA antagonist) into the anterior VTA markedly increased extracellular DA in the NAcc. In anesthetized rats, Yim and Mongenson [184] reported that GABA inhibited the discharge rate of DAergic neurons in the VTA, while application of picrotoxin increased the discharge rate of DAergic neurons. Hence, converging evidence suggests that GABA_A receptors in the VTA mediate tonic inhibition over DAergic neurons. In addition, VTA DAergic neurons that project to the NAcc appear to be activated by blockade of GABA_A receptors. Thus, since the projection from the VTA to the NAcc (mesoaccumbens DA system) has been implicated in reward-related processes [185, 186], one possible mechanism that underlies the blockade of EtOH-reinforcing effects by BDZ inverse agonists and specific GABA_A receptor antagonists may be activation of the mesoaccumbens DA system and, thereby, enhanced reinforcing effects.

While a vast and mature literature exists on the interactions between brain GABA and DA systems (see [187] for a review), the modulation of this interaction by BDZ ligands and, more specifically, inverse agonists is not as extensive (for a review see [188]). In general, these data suggest that inverse agonists can mimic the enhancing effects of stress on DA transmission in the prefrontal cortex. Specifically, systemically administered β -carbolines [e.g., beta-carboline-3-carboxylate methyl ester (β CCM), β CCE, FG 7142] have been shown to selectively increase DOPAC, or DOPAC–DA ratios [189, 190]. This increase in DA transmission has been more directly measured as an increase in cortical DA efflux using microdialysis techniques [191]. It is also worth noting that the EtOH antagonist RO15-4513 also increases prefrontal DOPAC [190]. The precise neuronal circuits underlying the BDZ modulation of cortical DA transmission, however, remains unclear because the vast majority of the studies have employed systemic drug injections (for a review see [188]). The effects of inverse agonists on subcortical DA neurotransmission have also been investigated. McCullough and Salamone [192] demonstrated that the inverse agonists FG 7142 (10–30 mg/kg) or β CCE (1.25–2.5 mg/kg) led to dose- and time-dependent increases in DA efflux. Coco et al. [193] examined BDZ ligand modulation in stress-induced DA transmission in the mesoamygdaloid system. Conditioned footshock increased homovanillic acid content in several regions of the amygdaloid and septal nuclei in the absence of any effects in cortical areas. Moreover, these effects were antagonized by diazepam. Collectively, these studies demonstrate the capacity of GABA antagonists and BDZ inverse agonists to modulate cortical and subcortical DA systems and provide support for proposing to use these agents as neuropharmacological tools to investigate GABAergic modulation of DA function.

14.6.5 Conceptual Framework for Hypothesis Generation and Interpretation of GABA–DA Interaction in Alcohol Drinking Behavior

It has become increasingly clear that alcohol-motivated behaviors in selected and outbred rat lines are regulated by multiple neurotransmitter systems [1, 9]. As stated previously in this review, a major task for alcohol self-administration investigators will be to determine the extent to which these neuronal systems singly and collectively regulate alcohol-seeking behaviors. We propose that GABAergic neurons may regulate alcohol's euphoric properties via the involvement of GABA within (in the VP) mesolimbic DA or opioid systems [1, 194]. The topography of the VP [64, 195] places it in a unique position to serve as a pivotal regulator of dopaminergic,

opioidergic, and GABAergic inputs that could control EtOH-motivated behaviors. However, the close proximity and coexistence of GABA and DA within this reward circuitry [177, 196, 197] makes DA a more likely candidate to interact with the GABA system. Previously, Legault et al. [198] have established a DA link between the ventral hippocampus (i.e., subiculum) NAcc and VTA, with DA activation being dependent on initial stimulation of the hippocampus and integrity of the NMDA receptor. We will argue (and present indirect evidence from the literature) that a negative GABA modulator, in particular one selective for the hippocampus, may augment DA to regulate reward-related behavior. In addition, VP GABAergic neurons have been shown to mediate the major DA output neurons of the VP [199]. Thus, we hypothesize in this review that both the VP and hippocampus, because of their high preponderance of GABA α_1 and α_5 receptor subunits, respectively, represent unique substrates to begin systematically testing a GABA–DA interaction hypothesis of alcohol-motivated behaviors. Finally, we will argue that an attempt to understand the GABA–DA interaction in the VP alone would be a gross oversimplification of how this complex interactional pathway functions to mediate alcohol-rewarded behavior.

14.6.6 Novel CNS GABAergic Substrates Regulating Alcohol-Motivated Behaviors

Despite the growing body of evidence for the GABA system in regulating EtOH reinforcement, much remains unknown about the role of specific GABA_A receptor subtypes. This primarily reflects (1) the paucity of high-affinity and selective ligands capable of discriminating among GABA_A receptors and (2) the heterogeneity of various subunits within the known alcohol reward circuitry [141, 143]. Figure 14.13 depicts this heterogeneity of the α subunits (the principal determinant of BDZ ligand affinity) within the alcohol reward loci using in situ hybridization and immunocytochemistry findings [141–143]. However, despite the remarkable heterogeneity within and among the brain reward loci, several substrates exhibit a preponderance of a single α subunit. These structures can be exploited for investigation of alcohol's rewarding effects. The probability of accurately delineating such structures in alcohol reward is markedly enhanced when a selective (albeit low- to moderate-selectivity) GABA_A receptor subtype ligand is employed.

14.6.7 Ligands with Preferential Selectivities for GABA_A Receptors Containing α_1 Subunit (GABA_{A1} Receptors)

β -Carboline-3-carboxylate-*t*-butyl ester (β CCt) and 3-propoxy- β -carboline hydrochloride (3PBC) were initially synthesized as “neutral” β -carboline antagonists [122, 200–202] with selectivity at the α_1 -containing GABA_A receptors (also known to as the BDZ1 receptor). Behavioral studies in several species (e.g., rats, mice, primates) show that both ligands can function as BDZ antagonists, exhibiting competitive binding site interaction with BDZ agonists over a broad range of doses [201–208]. Other studies have shown that both ligands produce anxiolytic effects in rodents [203], while β CCt potentiates the anticonflict response induced by α_1 subunit ligands in primates [205]. Thus, both β CCt and 3PBC are capable of displaying an agonist or antagonist profile depending on the behavioral task, species, and dose employed.

Figure 14.13 Distribution of GABA_A receptor containing subunits (e.g., $\alpha\beta 2/3\gamma 2$) in putative alcohol reward substrates based on in vitro immunocytochemistry [141, 142, 146], in situ hybridization [143, 146, 213, 214], and in vivo neurobehavioral [18, 19, 30, 37, 123, 125] studies. (See color insert.)

Hence, their behavioral pharmacological profile can best be described as that of “a partial agonist–antagonist” [19, 37].

Until recently, zolpidem and CL 218, 872 were the most selective ligands for the α_1 subunit (see [200]). Studies of recombinant receptors show βCCt exhibits greater than 10-fold selectivity for the α_1 over the α_2 and α_3 subunits and more than 110-fold selectivity for the α_1 over the α_5 subunit [19, 200] (see Table 14.1). Zolpidem has only a 5- and 15-fold greater selectivity at the α_1 subunit compared with α_2 and α_3 subunits, respectively. Neither βCCt nor zolpidem have significant affinities at the α_5 and α_6 subunits. 3PBC also displays a moderate level of selectivity for the α_1 subunit, exhibiting 9.8-, 13-, and 111-fold selectivity relative to the α_2 , α_3 , and α_5 subunits, respectively [37] (Table 14.1). Hence, βCCt and 3PBC exhibit the greatest binding selectivity of the currently available α_1 -subunit ligands reported to date [201, 209, 210].

14.6.8 Efficacies of βCCt and 3PBC in Modulating GABA Responses in Recombinant GABA_{A1,2,3,5} Receptors

Unlike the pharmacological profile of many other neuronal system ligands, the selectivity of GABA BDZ site ligands can also be described in relation to pharmacological efficacy. This efficacy is based on the capacity of a ligand to modulate GABAergic function [137]. As discussed below, there is some debate

TABLE 14.1 Affinity of α_1 (Top) and α_5 (Bottom) Selective Ligands

Compound	α_1	α_2	α_3	α_5	α_6 (DI), nM
β CCT	0.7	15	18.9	111	> 5,000
3PBC	5.3	52.3	68.8	591	> 1,000
3EBC	6.4	25.1	28.2	826	> 1,000
Zolpidem	27	156	383	10,000	> 10,000
CL 218, 872	57	1960	1160	561	> 10,000
Diazepam	14	20	15	11	> 3,000
ZK 93426	11	31	24	3	1,600
L-838,417	0.79	0.67	0.67	267	2.25
RO15-4513	3.3	2.6	2.5	0.26	3.8
RY023	197	143	255	2.61	58.6
RY024	27	26.3	18.7	0.4	5.1
RO15-1788	0.8	0.9	1.05	0.6	148

Note: In vitro **recombinant binding assay**. The affinity of compounds at GABA_A/BDZ receptor, subtypes was measured by competition for [³H]RO15-1788 (83 Ci/mmol; NEN) binding to Ltk cells expressing human receptors of composition $\alpha_1\beta_3\gamma_2$, $\alpha_2\beta_3\gamma_2$, $\alpha_3\beta_3\gamma_2$, $\alpha_5\beta_3\gamma_2$, and $\alpha_6\beta_3\gamma_2$. Cells were removed from culture by scraping into phosphate-buffered saline, centrifuged at 3000 g and resuspended in 10 mL of phosphate buffer (10 nM KH₂PO₄, 100 nM KCl, pH 7.4 at 4°C) for each tray (25 cm²) of cells. Radioligand binding assays were carried out in a volume of 500 μ L which contained 100 μ L of cells, [³H]RO15-1788 at a concentration of 1–2 nM and test compound in the range of 10^{−9}–10^{−5} M. Nonspecific binding was defined by 10^{−5} M diazepam and typically represented less than 5% of the total binding. *K*₁ values were calculated using the least-squares iterative fitting routine of RS/1 analysis software (BBN Research Systems, Cambridge, MA) and are either mean \pm SEM (standard error of the mean) or the means of two determinations which differed by less than 10%. Recombinant receptors expressed with either a β_3 or β_2 subunit have been shown to exhibit the same benzodiazepine receptor ligand affinities [37, 146, 246, 247].

in the literature as to whether a ligand's affinity or efficacy selectivity is the more salient factor in determining a ligand's capacity to function as an alcohol antagonist [4, 18, 123]. Hence, knowing the efficacy of putative anti-alcohol reward ligands across GABA_A receptors is indeed critical to knowledge of their neuromechanism of action. This is particularly the case with BDZs, insofar as ligands may have a different efficacies depending on their activity at a particular subunit. Hence, the efficacy of β CCT and 3PBC's has been investigated across all "diazepam-sensitive" receptors (i.e., receptors bearing α_1 , α_2 , α_3 , or α_5 subunits) and the α_4 subunit in the *Xenopus* oocyte assay [4, 37]. For comparison, the activities of the prototypical antagonists ZK 93426 and flumazenil were also evaluated. Figure 14.14 shows that β CCT exhibited either a neutral or low-efficacy agonist response at GABA α_1 (96 \pm 7%), α_2 (99 \pm 10%), α_3 (108 \pm 6%), and α_4 (107 \pm 5%) subunits compared to a normalized GABA response of 100% in its absence. However, a low-efficacy partial inverse agonist response was observed at the α_5 subunit (88 \pm 7% of the GABA response). Flumazenil exhibited an efficacy profile that was qualitatively similar to β CCT at the α_1 (99 \pm 5%), α_3 (118 \pm 7%), and α_5 (96 \pm 6%) subunits. At the α_2 subunit, flumazenil produced a low-efficacy agonist response (115 \pm 4%) while β CCT was GABA neutral (98 \pm 10%). Flumazenil also produced a qualitatively similar response to β CCT at the α_4 subunit, albeit the magnitude of GABA potentiation by

flumazenil far exceeded that of β CCt ($132 \pm 6\%$ vs. $108 \pm 6\%$, respectively). In contrast, ZK 93426 produced a clear agonist profile, potentiating GABAergic activity (see below).

3PBC acted as a modest positive modulator at α_1 -, α_2 -, α_3 -, and α_4 -containing receptors ($113 \pm 4\%$, $116 \pm 7\%$, $119 \pm 6\%$, $129 \pm 3\%$ of GABA response, respectively). At the α_1 through α_5 subunits, flumazenil exhibited an efficacy profile statistically similar to 3PBC ($p > 0.05$). At the α_1 through α_4 subunits, ZK 93426 exhibited a full agonist profile ($146 \pm 11\%$, $140 \pm 13\%$, $147 \pm 10\%$, $137 \pm 8\%$, respectively). These effects were statistically greater than 3PBC and flumazenil at the α_1 through α_3 subunits ($p < 0.05$). By comparison [211, 212], flunitrazepam, the full agonist, markedly enhanced GABAergic activity ($152 \pm 8\%$ to $164 \pm 3\%$) across the α receptor subunits (data not shown). At the α_5 subunit, each of the three antagonists exhibited a very weak negative profile which was indistinguishable from each other ($p > 0.05$).

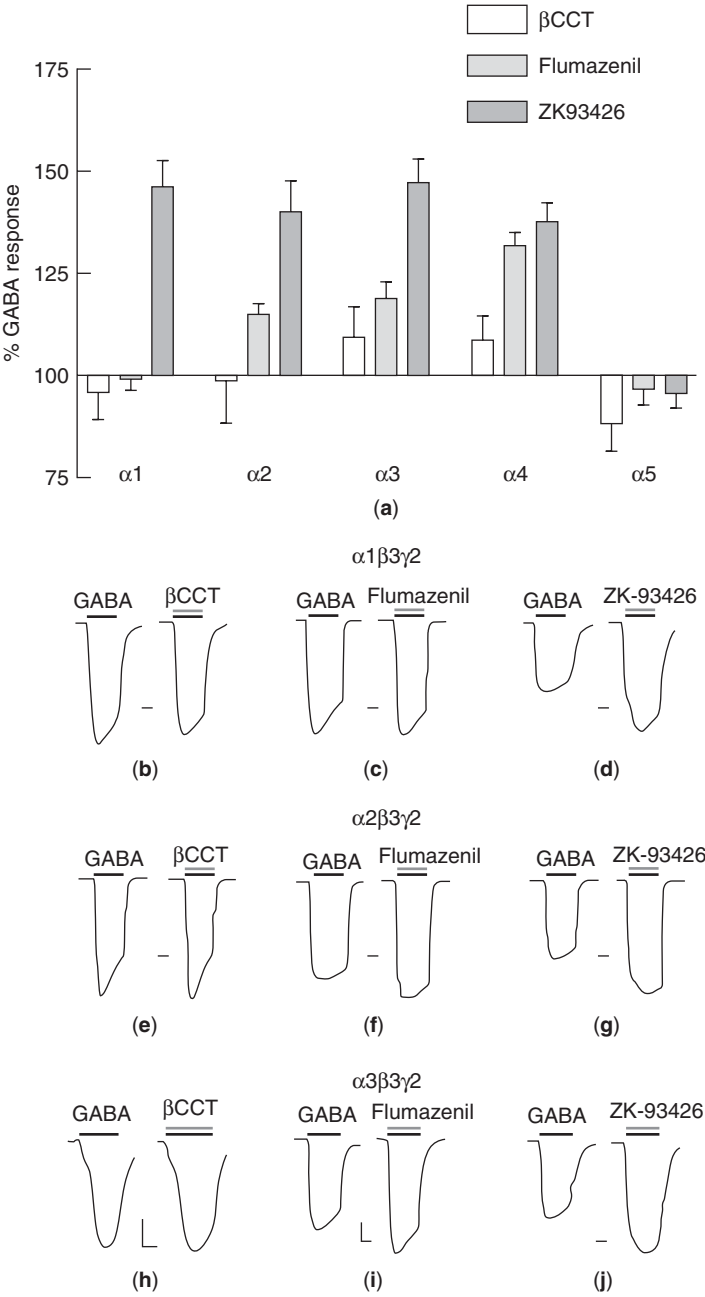

In summary, the efficacy data suggest a qualitatively similar profile for β CCt and flumazenil across recombinant GABA_A receptors bearing the α_1 to α_5 subunits. However, β CCt did not significantly affect GABA currents at the α_1 , α_2 , α_3 , or α_4 (Fig. 14.14) subunits; in contrast, flumazenil increased GABA currents at the α_2 ($p < 0.09$), α_3 ($p < 0.05$), and α_4 ($p < 0.01$) subunits relative to the control condition. The effects of 3PBC mirrored that of flumazenil at the α_2 , α_3 , α_4 , and α_5 subunits compared with the control condition (i.e., GABA alone) ($p < 0.01$) [37]. Hence, while β CCt is relatively GABA neutral (i.e., only a minute GABA potentiation) across all receptor subunits studied, 3PBC and flumazenil are partial agonists at some subunits (α_2 , α_3 , and α_4) and relatively GABA neutral at others (α_1 and α_5). In contrast, however, ZK 93426 produces full agonism at the α_1 to α_4 subunits and GABA-neutral activity at the α_5 subunit. It is possible that the low-efficacy agonist activity across multiple receptor subunits could account for the behavioral pharmacological profile observed with both β CCt and 3PBC in the in vivo behavioral studies noted above.

14.7 EMPLOYING LIGANDS WITH PREFERENTIAL SELECTIVITIES FOR α_1 SUBUNIT CONTAINING GABA_A RECEPTOR AS PHARMACOLOGICAL PROBES TO INVESTIGATE NOVEL ALCOHOL REWARD SUBSTRATES

14.7.1 Ventral Pallidum

Of the potential GABA_A receptors involved in the reinforcing properties of alcohol, evidence suggests the GABA_{A1} subtype within the VP may play an important role in regulating alcohol-seeking behaviors. First, the VP contains one of the highest densities of α_1 subunits in the mesolimbic system [142, 143, 213, 214] (see Fig. 14.15). Second, while a number of unilateral GABAergic projections exist across the reward circuitry from various brain substrates, dense reciprocal GABAergic projections exist from the VP to the NAcc [64, 215–217] (see Fig. 14.16). Third, acute EtOH administration has been reported to selectively enhance the effects of iontophoretically applied GABA in the VP, and these effects are highly correlated with [³H]zolpidem binding (an α_1 subunit selective agonist) [218, 219]. Finally, prior

reports have demonstrated that the VP plays a role in regulating the rewarding properties of psychostimulants and opioids [43, 194, 220]. Together, the above findings suggest a possible role for the VP GABA_A receptors in the euphoric properties of alcohol. We hypothesize that the VP might be functionally relevant in regulating alcohol-motivated behaviors.

14.7.2 Systemic Studies

The initial objective of these studies was to evaluate the selectivity of systemically administered β CCt and 3PBC to decrease responding maintained by EtOH presentation in P and HAD rats. Figure 14.17a shows the effects of β CCt (5–40 mg/kg) in P rats ($N=10$) on a concurrent schedule presentation of EtOH and saccharin when response rates are equated at basal levels [19]. All tested doses of β CCt significantly suppressed EtOH responding. Twenty-four hours post-drug administration the 40-mg/kg dose continued to suppress EtOH responding by 75% of control levels. Further, similar to the effects observed with ZK 93426 and CGS 8216 [166] (nonselective BDZ antagonists), no significant suppression occurred on saccharin responding on day 1 or 24 h post-drug administration (bottom portion

Figure 14.14 Modulation of GABA_A $\alpha_1\beta_3\gamma_2$, $\alpha_2\beta_3\gamma_2$, $\alpha_3\beta_3\gamma_2$, $\alpha_4\beta_3\gamma_2$, and $\alpha_5\beta_3\gamma_2$ receptor subunit combinations expressed in Ltk cells by β CCt (open bars), flumazenil (shaded bars), and ZK 93426 (black bars). A saturating concentration (1–10 μ M) was coapplied over voltage-clamped oocytes along with an EC₅₀ of GABA. (a) Each value is the mean % GABA response \pm SD of at least four separate oocytes. Actions of β CCt, flumazenil, and ZK 93426 on recombinant GABA_A receptor subtypes. Figure 14.15 Distribution of GABA_A receptor containing subunits α_1 - $\alpha_6\beta_2\gamma_2$ in rat CNS based on immunocytochemistry studies by Turner and colleagues [142]. (See color insert.)

of Fig. 14.17a). Figure 14.17a shows basal operant response rates for EtOH and sucrose were very similar in the HAD rats. The 1- to 10-mg/kg β CCt injections dose dependently suppressed responding maintained by alcohol. The bottom portion of Figure 14.17b shows that β CCt suppressed responding maintained by sucrose only with the 10-mg/kg dose.

Figure 14.18 shows data for P rats following i.p. administration of 1–20 mg/kg of 3PBC. Prior to 3PBC administration the no-injection control (EtOH 201 ± 51 responses; saccharin 153 ± 23 responses) and the Tween-20 vehicle (EtOH 191 ± 42 ; saccharin 161 ± 41) conditions were similar. Hence, these data were pooled and used to compare against the drug treatment. The black bars of Figure 14.18 show that 3PBC produced a significant dose-related reduction on EtOH-maintained responding, reducing responding by as much as 35–84% of control levels. The hashed bars of Figure 14.18 show that, in contrast to the effects observed on alcohol responding, the lower 3PBC doses (1–10 mg/kg) markedly and significantly elevated responding maintained by saccharin, while the 20-mg/kg dose markedly and significantly suppressed responding. Together, these data show that, given systemically, β CCt and 3PBC are capable of selectively reducing EtOH-maintained responding. The data also demonstrated that across two alcohol-selected rat lines, β CCt can function as an antagonist of EtOH-seeking behaviors and not suppress responding for a palatable noncaloric or caloric solution given concurrently with EtOH.

Figure 14.16 Illustration of both unilateral and reciprocal GABAergic projections in putative alcohol reward substrates based on histological mapping studies [64, 87, 88, 94, 95, 215–217]. (See color insert.)

14.7.3 Microinjection Studies

The second objective employing β CCt and 3PBC was to *directly* test the hypothesis that the GABA_{A1} receptor within the VP plays an important role in regulating alcohol-seeking behaviors. It should be recalled that a substantial number of α_1 -subunit-containing GABA_A receptors exist within the VP, while exceedingly low or nondetectable levels of the other α subunits (e.g., α_2 , α_3 , α_4 , α_5 , and α_6) are found within the VP [142, 143, 213, 214]. Figure 14.19a shows behavioral data for P rats bilaterally infused with β CCt (5–40 μ g) in the VP compared with the no-injection baseline (i.e., BL) and the artificial cerebral spinal fluid (aCSF) control conditions. β CCt dose dependently reduced EtOH-maintained responding relative to control conditions. In contrast, β CCt was without effect on responding maintained by saccharin (Fig. 14.19a). Finally, β CCt failed to alter responding maintained by EtOH or saccharin following infusion into the NAcc or caudate putamen (CPu) area (Fig. 14.19b). Hence, β CCt displayed both reinforcer and neuroanatomical specificity.

Figures 14.19c–e show data for HAD rats following administration of β CCt (5–40 μ g). The HAD rats were trained to lever press for alcohol only; HAD rats do not lever press for alcohol in significant quantities when concurrently presented with highly palatable reinforcers [4]. To further substantiate the neuroanatomical specificity of the GABA_{A1} receptor in alcohol-related behaviors, HAD rats received a unilateral implant in the VP and a second implant in either the CPu or NAcc.

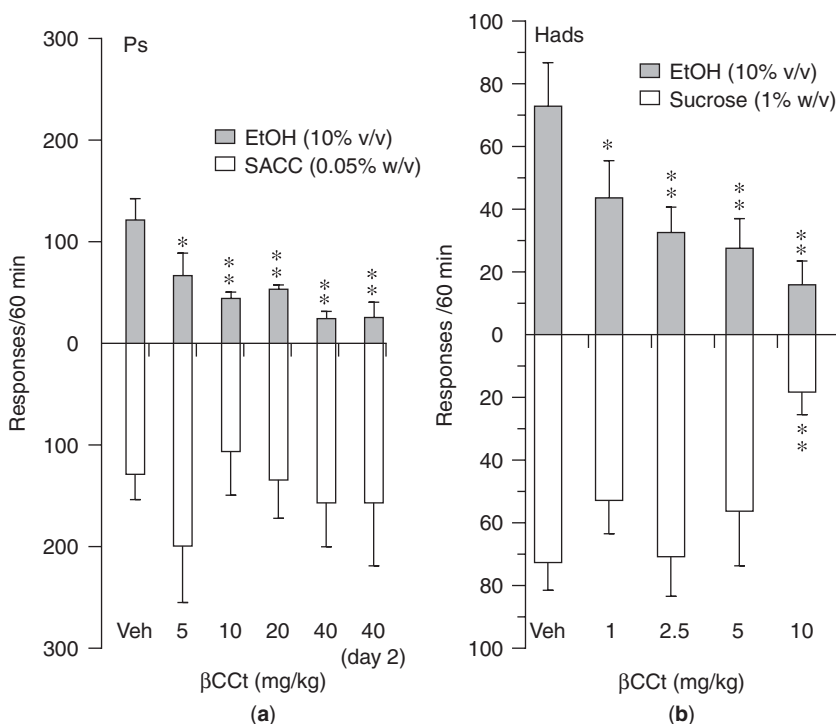

Figure 14.17 Dose-response of systemic β CCt injections (i.p.) in (a) P (Ps) (5–40 mg/kg) and (b) HAD-1 (Hads) (1–10 mg/kg) rats. P rats ($N=11$) performed under a concurrent FR4 schedule for EtOH (10% v/v) and saccharin (0.05% w/v). HAD-1 rats ($N=11$) performed under an alternate-day access paradigm, wherein they received EtOH (10% v/v) on day 1 and sucrose (1% w/v) on day 2. At 15 min after the i.p. injections, rats were placed in the operant chamber to lever press for a 60-min session. (**) $p<0.01$ and (*) $p<0.05$ vs the control condition values by ANOVA and post hoc Newman–Keuls test. Bars represent means \pm SEM. Adapted from June et al., 2003.

Figures 14.19c–e show rates of responding maintained by EtOH following unilateral microinjection of the 0.5- to 7.5- μ g doses of β CCt into the VP of HAD rats. Compared with the aCSF control condition, β CCt dose dependently reduced EtOH responding. In addition, 24 h post-drug administration the 2.5- to 7.5- μ g doses continued to reduce responding by as much as 54–63% of control levels. In contrast, unilateral infusions of β CCt into the CPu/NAcc areas were completely ineffective in altering alcohol-maintained responding (Figs. 14.19d,e).

A study by Harvey et al. [37] evaluated the efficacy of bilaterally administered 3PBC in the VP or NAcc/CPu employing a similar experimental design as June et al. [19]. 3PBC (0.5–40 μ g) was found to dose dependently and selectively reduce alcohol-maintained responding relative to the control condition (see Fig. 14.20). Only the 40- μ g dose nonsignificantly reduced saccharin responding. To determine the neuroanatomical specificity of the VP α_1 subunit modulation of alcohol-maintained responding, Harvey et al. [37] evaluated the capacity of 3PBC to reduce alcohol-motivated behaviors in the NAcc/striatum, a locus reported to be devoid of the α_1 receptor

Figure 14.18 Dose–response of systemic (0.0–20 mg/kg; $n = 13$) injections of 3PBC on a concurrent FR4 schedule for EtOH (10% v/v) and saccharin (0.05% w/v) responding during the 1-h operant session. (*) $p < 0.05$ versus the control condition values by ANOVA and post hoc Newman–Keuls test. Error bars indicate means \pm SEM. The two control conditions were pooled in the systemic group and compared against the drug treatment conditions. BL, Baseline; Veh, vehicle control. Adapted from Harvey et al., 2002.

subunit [141–143, 214]. Similar to the β Cct treatments, responding maintained by EtOH and saccharin (Fig. 14.20b) following 3PBC in the NAcc/CPu locus was not altered. Hence, these data indirectly confirm the significant topography of the GABA_{A1} receptor in the pallidal area of the P rats for EtOH-maintained responding [213, 214].

Taken together, these data show that β Cct and 3PBC in the VP are capable of selectively reducing EtOH-maintained responding with little if any effect on responding for a palatable saccharin/sucrose reinforcer. Since both β Cct and 3PBC are moderately selective for the GABA_{A1} and a high density of these receptors are located in the VP, it is reasonable to hypothesize that the attenuation seen by these agents are mediated at least in part via the GABA_{A1} receptors. Further, some degree of neuroanatomical specificity was also observed since neither β Cct nor 3PBC altered EtOH responding when infused into the NAcc or CPu.

14.8 ORAL ADMINISTRATION OF β CCT OR 3PBC PRODUCES PROLONGED REDUCTION ON ALCOHOL SELF-ADMINISTRATION: DIRECT COMPARISON WITH OPIOID RECEPTOR ANTAGONIST NALTREXONE

To evaluate potential pharmacotherapies for alcohol dependence in rodents, it is necessary to determine their capacity to reduce alcohol drinking via the oral route. Employing the oral gavage route of administration, June et al. (unpublished)

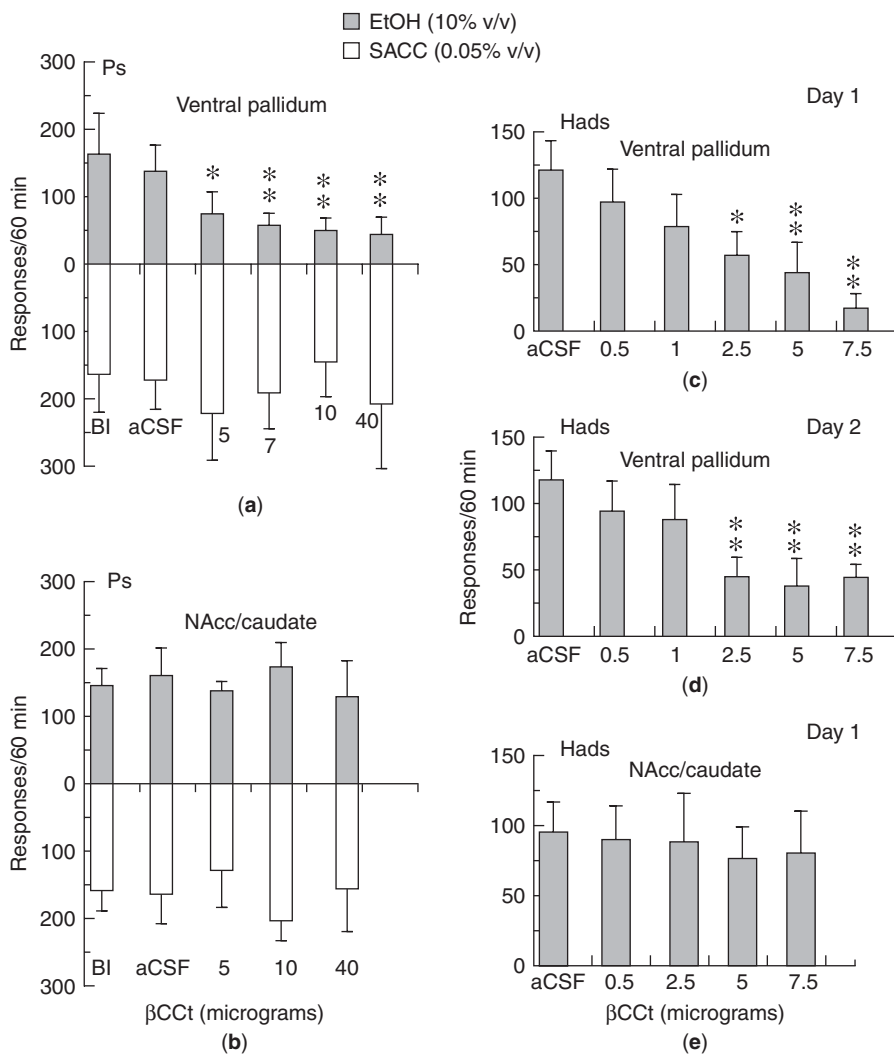

Figure 14.19 (a) Performance of female P rats ($n=11$) on a concurrent FR4 schedule for EtOH (10% v/v) and saccharin (0.05% w/v) following bilateral infusions of β CCt (0.0–40 mg) in the VP. (b) Performance of control female P rats ($n=7$) on a concurrent FR4 schedule for EtOH (10% v/v) and saccharin (0.05% w/v) following bilateral infusions of β CCt (0.0–40 mg) in the NAcc/CPu areas. (c, d) Performance of female Had rats ($n=9$) on an FR4 schedule for EtOH (10% v/v) following unilateral infusions of β CCt (0.0–7.5 mg) in the VP on the first day of infusion and 24 h post-drug administration. (e) Performance of the same female Had rats in (c) ($n=9$) on an FR4 schedule for EtOH (10% v/v) following unilateral infusions of β CCt (0.0–7.5 mg) in the NAcc/CPu areas on the first day of infusion. (**) $p < 0.01$ and (*) $p < 0.05$ compared with the baseline (BL) and aCSF conditions using post hoc Newman–Keuls tests. Error bars indicate means \pm SEM. Adapted from June et al., 2003.

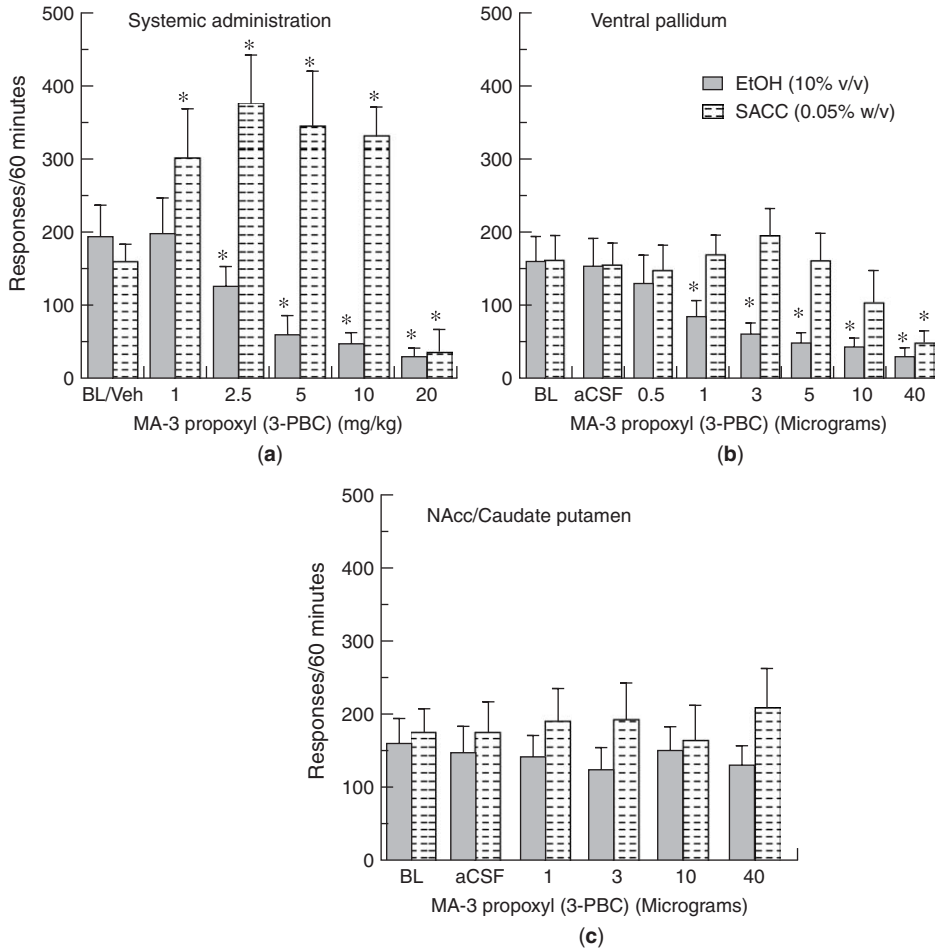

Figure 14.20 Dose–response bilateral infusions of 3PBC (0.5–40 μ g) in the VP (a; $n = 12$) and NAcc/CPu (neuroanatomical control loci) (b; $n = 7$) on a concurrent FR4 schedule for EtOH (10% v/v) and saccharin (0.05% w/v) responding during the 1-h operant session. (*) $p < 0.05$ versus the control conditions values by ANOVA and post hoc Newman–Keuls test. Error bars indicate means \pm SEM. BL, Baseline; Veh, vehicle control. Adapted from Harvey et al., 2002.

evaluated the actions of β CCt and 3PBC (0–75 mg/kg) on alcohol-motivated responding. The nonselective opioid antagonist naltrexone was used as a reference agent, since it is well established as an alcohol antagonist that reduces both alcohol cravings and intake [221]. Figure 14.21 shows data for naltrexone on day 1, 30 min after drug administration. Naltrexone produces clear dose-dependent reduction on alcohol responding on day 1; however, no effects on alcohol responding were observed on day 2. Figure 14.22 shows that, similar to naltrexone, dose-dependent reductions were observed on alcohol responding on day 1, 30 min following β CCt administration; however, in contrast to naltrexone, marked reductions on alcohol drinking were still detectable 24 h postdrug. 3PBC also produces dose-dependent reductions on alcohol responding on day 1, and similar to β CCt, the marked reductions on alcohol drinking were still apparent 24 h later (Fig. 14.23). At the

Figure 14.21 Responding for 10% EtOH (v/v) expressed as a percent of baseline line following oral administration of naltrexone (15, 30, 50, 75 mg/kg); **, $p < 0.01$.

highest tested dose (e.g., 75 mg/kg) neither β CCt nor 3PBC altered responding maintained by sucrose; however, naltrexone profoundly reduced sucrose responding. Together, these data show that both β CCt and 3PBC are as effective as naltrexone in reducing alcohol drinking following acute administration. However, β CCt and 3PBC are far superior to naltrexone in their duration of action on alcohol responding, with suppression observed for at least 24 h postadministration. In addition, unlike naltrexone, neither β CCt nor 3PBC reduced sucrose (a highly palatable caloric reinforcer) responding. These findings suggest that β CCt and 3PBC are excellent candidates for reducing alcohol intake and cravings in humans and are not likely to nonselectively reduce other consummatory behaviors such as feeding and drinking.

14.8.1 Oral Efficacy of β CCt and 3PBC in Reducing Anxiety in Alcohol-Preferring Rats

The in vitro data presented above suggest that both β CCt and 3PBC produce agonist activity at some GABA_A receptors while exerting GABA neutral/antagonist activity at others. In many instances, in vitro pharmacology does not extrapolate to whole-animal pharmacology. However, given that β CCt and 3PBC produced a sustained reduction in alcohol drinking behavior, an added advantage of these agents would be a demonstrated effectiveness in reducing anxiety. It is well established in addiction psychiatry that anxiety and alcohol abuse are comorbid disorders [222]. Furthermore, it is possible that anxiety may predispose subjects to initiate alcohol drinking behaviors [223, 224]. Hence, the oral effectiveness of β CCt and 3PBC was evaluated in reducing anxiety (assessed using the elevated-plus maze) in alcohol-preferring rats. Gavage of β CCt and 3PBC was indeed effective in reducing the anxiety in P rats (Fig. 14.24) with β CCt also effective in reducing anxiety in HAD rats. Compared with the NP rat, the P rat is more “anxious” in the plus maze assay [224]. Thus, this behavioral assay is well suited for the assessment of novel anxiolytics in P rats. Taken together, the oral effectiveness of β CCt and 3PBC as anxiolytics combined with their oral efficacy in reducing alcohol drinking behavior makes both of these compounds

Figure 14.22 Responding for 10% EtOH (v/v) following oral administration of β CCt (25, 40, 75 mg/kg) (a) and 24 h postadministration (b); **, $p < 0.01$.

ideal as prototype pharmacotherapeutic agents in reducing alcohol drinking behaviors in humans.

14.9 EMPLOYING LIGANDS WITH PREFERENTIAL SELECTIVITIES FOR α_5 -SUBUNIT-CONTAINING GABA_A RECEPTORS AS PHARMACOLOGICAL PROBES TO INVESTIGATE NOVEL ALCOHOL REWARD SUBSTRATES: CA1 AND CA3 HIPPOCAMPUS

While GABA_{A5} receptors are minor constituents of the total GABA_A receptor pool, immunocytochemical, in situ hybridization, and radioligand binding studies show that the CA1, CA2, and CA3 fields are enriched in this subunit compared with other brain areas [141, 143, 225]. Only, low or nondetectable levels of other subunits can be localized within the hippocampus. The CA1 and CA3 hippocampal fields are

Figure 14.23 Responding for 10% EtOH (v/v) following oral administration of 3PBC (25, 40, 75 mg/kg) (a) and 24 h postadministration (b); **, $p < 0.01$.

particularly interesting candidate sites for the study of alcohol-motivated behaviors since projections from the CA1 and CA3 fields, via the subiculum, innervate several putative EtOH reward substrates [e.g., NAcc, amygdala, bed nucleus of the stria terminalis (BNST), hypothalamus, olfactory tubercle] [215, 226, 227].

RY 023 (*tert*-butyl-8-(trimethylsilyl) acetylene-5,6-dihydro-5-methyl-6-oxo-4*H*-imidazo-[1,5a] [1,4]-benzodiazepine-3-carboxylate) (Table 14.2) is one of a series of 8-substituted imidazobenzodiazepine inverse agonists [145, 228, 229] developed from the anti-EtOH agent RO 15-4513 [132]. RY 023 exhibits both high binding affinity ($K_i \sim 2.7$ nM) and selectivity (~ 75 -fold) at recombinant GABA_A receptors composed of $\alpha_5\beta_2\gamma_2$ subunits [229] (see Table 14.1). RY 023 acts as a negative modulator at the $\alpha_1\beta_3\gamma_2$, $\alpha_2\beta_3\gamma_2$, and $\alpha_5\beta_3\gamma_2$ receptor subunits, inhibiting GABA-evoked current responses of voltage-clamped *Xenopus* oocytes by approximately 40–55%. The efficacy of the imidazobenzodiazepines RO 15-4513 and RO 15-1788 (flumazenil) were also examined at the α_1 , α_2 and α_5 subunits. These parent compounds were

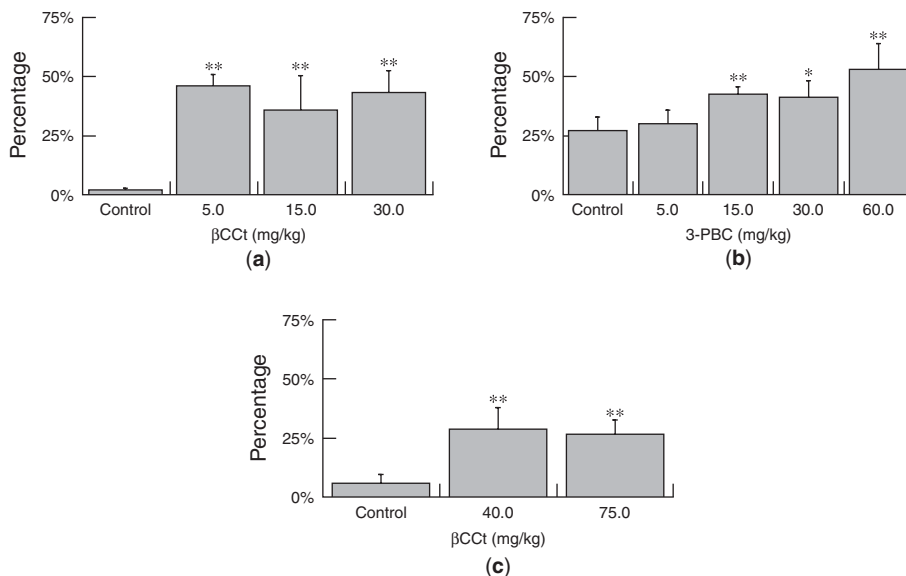

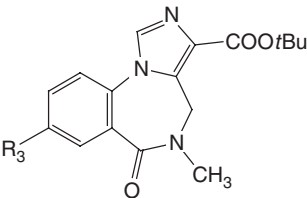

Figure 14.24 Percent of total time spent in open arms of an elevated-plus maze following oral administration of β CCt (5, 15, 30 mg/kg) (a) and 3PBC (5, 15, 30, 60 mg/kg) (b) in P rats and (40 and 75 mg/kg) in HAD rats (c); (*) $p < 0.05$ and ** $p < 0.01$.

selected since June et al. [18] were interested in evaluating the degree to which modification at position 8 (which produced the α_5 selectivity) [18, 228, 229] would change the imidazobenzodiazepine's capacity to modulate GABA at specific receptor subtypes. RO 15-4513 was also selected to compare the intrinsic activity of a reference alcohol antagonist (see [132, 230, 231]) with RY 023. RO 15-4513 produced a very modest inhibition of GABA current at the α_1 and α_2 subunits ($86 \pm 3\%$ and $93 \pm 1\%$ control response, respectively), while exhibiting no efficacy at the α_5 subunit ($99.5 \pm 4.1\%$ control response). RO 15-1788 (flumazenil), the competitive antagonist [232–234], acted as a modest positive modulator at the α_2 subunit ($115 \pm 4\%$ control response) and exhibited no efficacy at either the α_1 or α_5 subunit.

Taken together, these data reveal several important potency and efficacy differences between RY 023 and the alcohol antagonist RO 15-4513. First, the selectivity of RY 023 for the α_5 receptor subunit is higher than RO 15-4513 (see Table 14.1). Second, the magnitude of GABAergic reduction with RY 023 is far greater than that of RO 15-4513 at the α_1 , α_2 and α_5 receptor subunits [18]. Third, RO 15-4513 exhibits an efficacy profile similar to that of RO 15-1788 at the α_2 and α_5 subunits [18]. Hence, it is possible that the antialcohol properties of the two inverse agonists may be differentially regulated (see [123, 125]).

June and colleagues [18] tested the hypothesis that α_5 subunits of the CA1 and CA3 hippocampal fields would regulate EtOH-motivated behaviors in the P rat (also see [123, 125]). To accomplish this, the actions of bilateral and unilateral micro-injections of RY 023 in the CA1 and CA3 hippocampal fields were evaluated for their capacity to reduce EtOH-maintained responding. The degree of neuroanatomical specificity was examined using both bilateral and unilateral control injections into the

NAcc and VTA. Unlike the hippocampal fields, these brain areas possess higher levels of α_2 - and α_1 -subunit expression, respectively [141–143]. The specificity of RY 023 on consummatory responding was evaluated by determining the effects of RY 023 in P rats whose response rates for EtOH (10% v/v) and saccharin solutions (0.05% w/v) were similar at basal levels.

Figure 14.25a shows rates of responding maintained by EtOH (upper panel) following microinjection of the 1.5- to 20- μ g doses of RY 023 into the CA1 (dorsal and CA3 (ventral) hippocampus. RY 023 produced a dose-related suppression on EtOH-maintained responding. The lower panel shows that RY 023 selectively reduced EtOH responding, reducing saccharin responding only at the highest tested dose (20 μ g). When ZK 93426 was administered immediately prior to RY 023, it attenuated the RY 023-induced suppression on EtOH-maintained responding, suggesting the suppression was mediated via actions at the BDZ site of the GABA

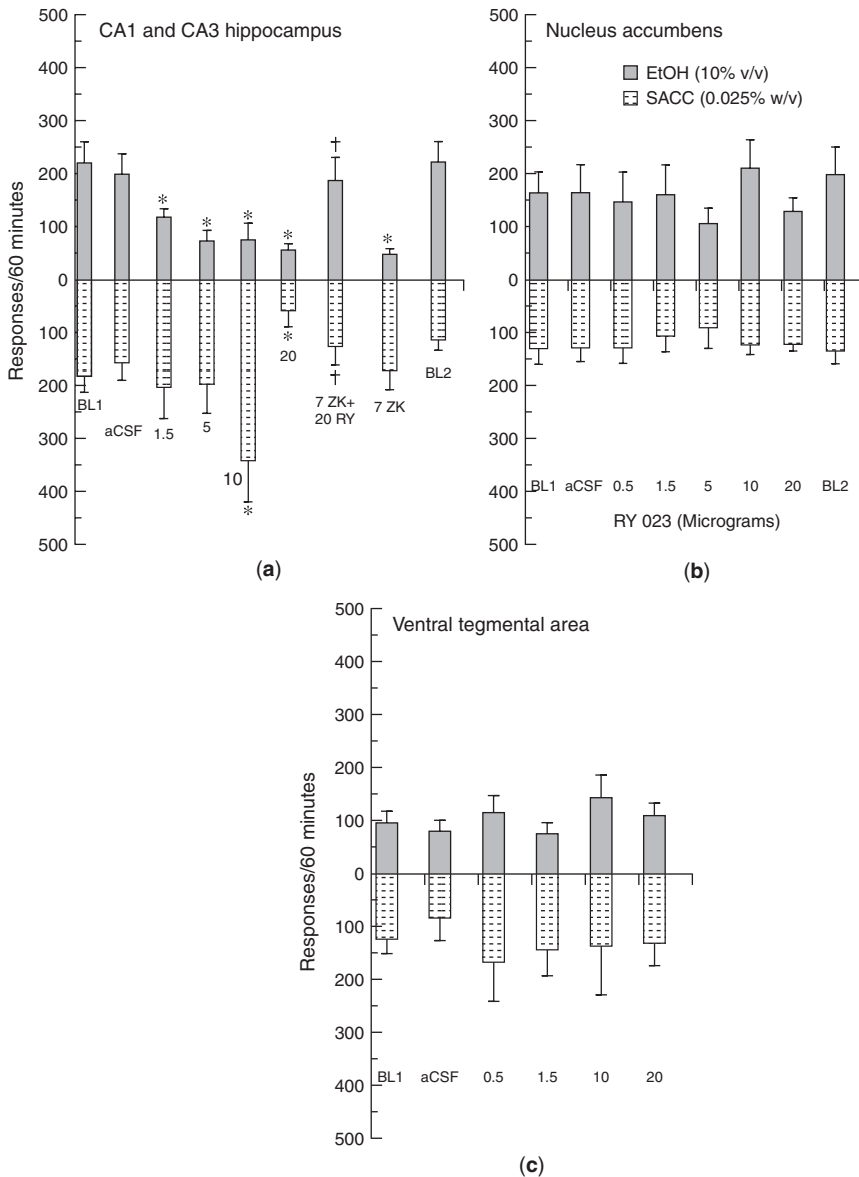

Figure 14.25 Dose–response of bilateral infusions of RY (0.0–20 µg) in the hippocampus ($n=9$) (a), NAcc ($n=9$) (b), and VTA ($n=10$) (c) on a concurrent FR4 schedule for EtOH (10% v/v) and saccharin-maintained (0.025% w/v) (SACC) responding. Immediately after the microinfusions, rats were placed in the operant chamber to lever press for a 60-min session. (*) $p < 0.05$ versus the no-injection control conditions (BL1 and BL2) and aCSF control condition values by ANOVA and post hoc Newman–Keuls test ($n=9$). Error bars represent \pm SEM. (†) $p < 0.01$ versus the 20 µg RY alone condition by ANOVA and post hoc Newman–Keuls test ($n=9$). ZK, the competitive BDZ antagonist, completely reverses the suppression by RY on EtOH and saccharin-motivated responding. RY was without effect on EtOH or saccharin-maintained responding in the NAcc and VTA. Adapted from June et al., 2001.

receptor complex Figures 14.25b,c show that, in addition to reinforcer selectivity, RY 023 was anatomically selective. Specifically, bilateral infusion into the NAcc or VTA was without effect on responding maintained by EtOH (upper panel) and saccharin (lower panel). Unilateral infusions of RY 023 produced a clear dose-dependent suppression on EtOH-maintained responding. With the exception of the highest tested dose (40 μ g), reinforcer selectivity was also observed, as was neuroanatomical selectivity, with no effects on EtOH-maintained responding observed in the NAcc or VTA. RY 023 also failed to alter saccharin-motivated behaviors in the NAcc and VTA.

The above findings provide the *first* demonstration that GABA_A receptors containing α_5 subunits in the hippocampus play a critical role in regulating alcohol-seeking behavior [18]. The findings are supported by recent research with outbred rats [125] and a related α_5 subunit selective ligand, RY 024, in P rats [123]. Finally, previous work has shown that an α_5 agonist substitutes for alcohol in primate drug discrimination studies [235]. Thus, these findings suggest that the hippocampus/hippocampal projection sites may be functionally relevant in regulating EtOH-motivated behaviors.

The precise GABA–hippocampal pathway(s) in which the GABA_{A5} selective ligands modify EtOH reinforcement/related responding is unknown; it has been hypothesized that GABA_A BDZ neuroanatomical circuits within the hippocampus may initiate activation of underlying DA substrates in the mesoaccumbens circuitry to contribute to the reinforcing properties of EtOH [18]. The functional role of conditioning stimuli in the onset and maintenance phases of alcohol-motivated drinking may also be important. It should be recalled that BDZs have long been proposed to modulate learning and memory processes via the hippocampus [236]. We conclude that the GABA–hippocampal pathway may represent an “extension” of the mesolimbic EtOH reward circuitry as has been proposed by Koob and colleagues [52]. Thus, the hippocampus may be an important *target* in the development of potential pharmacotherapies for alcohol addiction and dependence. The *Xenopus* oocyte studies demonstrated that the capacity of BDZs to attenuate EtOH-motivated responding was not directly related to their intrinsic efficacy; rather, their selectivity and differential potency to attenuate EtOH-seeking behaviors appear to be more related to their affinity and selectivity at different GABA_A-containing receptor subunits. However, it is possible that the *in vitro* efficacy observed in the *Xenopus* oocyte assay may not reflect the *in vivo* efficacy in an animal model of alcoholism following BDZ administration.

14.10 SUBUNIT SELECTIVITY VERSUS INTRINSIC EFFICACY

The rank-order potencies of BDZ site ligands to attenuate EtOH intake are not correlated with either rank-order potencies to inhibit GABA $^{36}\text{Cl}^-$ conductance or enhance ^{35}S -*t*-butylbicyclopophosphorothionate (TBPS) binding [237]. While the ^{36}Cl flux and TBPS binding assays in brain tissues employ heterogenous subunit populations, with the resulting value obtained representing an “average efficacy,” the *Xenopus* oocyte system permits efficacy to be determined at any different subunit–complementary DNA (cDNA) combinations [140, 211, 212]. In the *Xenopus* system RO 15-4513 was essentially GABA neutral at the α_2 - and α_5 -subunit-containing

receptors and slightly GABA negative at the GABA_{A1} receptor. These data are in agreement with previous oocyte studies [29, 211, 212] and work by Wong and Skolnick [238] employing the “GABA shift” assay. The findings with RO 15-4513, however, contrast those with RY 023 and ZK 93426, where the GABA-evoked current is negatively and positively modulated, respectively, at the α_1 and α_2 receptor subunits. Nevertheless, despite the three different intrinsic activity profiles, each ligand was highly effective in attenuating EtOH-motivated behaviors [78, 156, 161, 166, 237]. Thus, while both efficacy and subunit selectivity may interact to effectively alter EtOH-motivated behaviors, the evidence in this review strongly suggests that subunit selectivity may be the critical factor in determining the capacity of a ligand to function as an effective alcohol antagonist. Several investigators suggest that efficacy not only is dependent on subunit composition but also is actually defined by it [145, 162a, 238, 239].

14.11 CONCLUSIONS

Research on the substrates and circuitry regulating alcohol self-administration has experienced enormous growth over the past decade. The primary purpose of this review was to provide the reader with relatively new research findings that have been critical in the delineation of novel brain reward substrates that can be targeted in the potential development of pharmacotherapeutic prototypes for alcohol addiction and dependence in humans. Alcohol-dependent individuals represent a heterogeneous group [19, 240–242]. Hence, it is unlikely that a single pharmacological treatment will be effective for all alcoholics. To this end, a better understanding of the neuromechanisms which regulate alcohol-seeking behaviors and the design of clinically safe and effective drugs that reduce alcohol addiction and dependence remain a high priority in alcoholism research [243–245].

In this review, we presented data implicating novel substrates and circuitry within the dopaminergic and GABAergic systems in alcohol reward. Prior to presenting these data, however, the significance of an optimal animal model of alcoholism and its integration with appropriate behavioral and neuroanatomical paradigms to accurately interpret findings obtained from alcohol self-administration studies were discussed. Relatively new data that implicated brain loci such as the VP, BST, and LH in regulating alcohol-motivated behaviors within the DA systems were also presented. Our conceptual framework was based on the premise that GABA mediates its actions on alcohol self-administration via interaction with the DA system [19, 37]. Indeed, current studies are underway in our laboratory showing that in many cases this DAergic regulation of alcohol intake can in fact be modulated via GABA receptors in other mesolimbic brain reward areas [104]. Finally, June et al. presented compelling data showing that, using a multidisciplinary approach (e.g., medicinal chemistry, molecular biology, behavioral pharmacology, neuroanatomy), it was indeed feasible to exploit the GABAergic system in the potential development of pharmacotherapies for alcohol addiction and dependence in humans (but see [245]). The primary GABA_A receptor candidates in these efforts were the α_1 and α_5 receptor subunits. However, the research efforts exploiting the α_1 receptor subunit demonstrating the oral effectiveness of β CCt and 3PBC as anxiolytics, combined with their oral efficacy in reducing alcohol drinking behavior, are compelling. This seminal

research on β CCt and 3 PBC should set the stage for further investigation in the coming years for evaluation of these agents as prototype pharmacotherapeutic agents in reducing alcohol drinking behaviors in human alcoholics.

15.1 OVERVIEW

Nicotine is the drug delivered upon tobacco use that defines the dependence and withdrawal syndromes as recognized by the World Health Organization (WHO) and

American Psychiatric Association (APA) [1, 2]. Many other potentially psychoactive substances are present in tobacco and/or the smoke of burned tobacco [3], but as concluded by Lewin in the 1920s, “the decisive factor in the [psychic] effects of tobacco, desired or undesired, is nicotine” [4, p. 256]. As a pharmacological agent with diverse and powerful neuronal effects and an important historical role in the development of neuroscience research strategies even before the term *neuroscience* was used, nicotine is fascinating to study.

Nicotine itself is not without toxicity, but at doses typically ingested by tobacco users, its direct contribution to disease is comparatively small relative to the more than 60 carcinogens, carbon monoxide, and many lung and cardiovascular toxins produced by tobacco cigarette smoking. Its role in tobacco-caused disease is primarily to sustain high and persistent levels of toxic tobacco smoke exposure. Thus, most tobacco-caused disease may be considered side effects of nicotine dependence. From a public health perspective, then, nicotine is critical in the scope and persistence of a global tobacco epidemic that is so devastating that it led to the first-ever international treaty negotiated by the WHO, put into force in 2005 [5]. This treaty, in turn, has already begun to drive additional research on nicotine and tobacco as part of its strong advocacy of a public health-driven demand reduction approach to controlling tobacco-caused disease.

Nationally, cigarette smoking has been cited as “the leading cause of preventable death in the United States” and is associated with profound health-related and financial costs [6, 7]. In terms of health costs, cigarette smoking causes approximately 442,398 premature deaths yearly [7]. Projections based on current smoking prevalence rates predict that, among persons who are currently younger than 18, approximately 6.4 million will die prematurely from a tobacco-related illness [7]. Financially, smoking costs approximately \$157 billion in annual health-related economic losses [6].

This chapter is intended to provide a state-of-the-art review of the pharmacology of nicotine to lay the foundation for furthering the understanding of nicotine’s role in tobacco use and its potential use as a treatment for tobacco use disorders. Research in recent decades involving the understanding, prevention, and treatment of tobacco dependence has already led to breakthroughs that are saving lives, but much has yet to be done. Based on the current course, if stronger actions are not developed and implemented, more than 1 million people will die prematurely every 2.5 years in the United States for decades to come, and approximately one-half billion of current smokers will perish globally. As recognized by the WHO, in its treaty, research is vital to guide public health policy [5]. We begin the chapter with a review of nicotine pharmacology (Section 15.2), followed by a review of pharmacologically based treatments for tobacco dependence (Section 15.3), and conclude with a section on public health policy implications.

15.2 PHARMACOLOGY OF NICOTINE

15.2.1 Overview

This section focuses on nicotine pharmacology (Section 15.2.2), namely nicotinic acetylcholine receptors (nAChRs), the neurobiological mechanisms and/or functional adaptations associated with nicotine reinforcement (Section 15.2.3),

dependence and tolerance (Section 15.2.4), withdrawal (Section 15.2.5), and nicotine pharmacokinetics (Section 15.2.6). The content (e.g., selection and order of topics) presented in Sections 15.2.2–15.2.5 has been adapted from Markou, Koob, and Henningfield (2003) [8].

15.2.2 Nicotinic Acetylcholine Receptors

Nicotine was first isolated from the leaves of tobacco, *Nicotiana tabacum*, in 1828 by Posselt and Reiman. It is a natural liquid alkaloid structurally similar to acetylcholine (ACh) that interacts with specific nAChRs in the central and peripheral nervous systems [9–11]. Nicotine and other nicotinic acting agents were used by Langely and colleagues in the 1890s and early twentieth century to explore the function and structure of the nervous system. They employed pharmacological tools, including the study of dose–response relationships, temporal and dose-related aspects of tolerance development and loss, and interactions among agonists and antagonists. This work led Langley (1905) to postulate the existence of some “receptive substance” which mediated the effects of nicotine and other agents and which would explain the selective action of differing chemicals on the same muscular and organ systems.

It is now known that nicotine produces its varied effects by binding to nAChRs, of which there are two categories, muscular and neuronal [12]. These receptors vary in their expression and function. For instance, muscular nAChRs are expressed in mature skeletal neuromuscular junctions while neuronal nAChRs are expressed in the autonomic ganglia and the central nervous system (CNS) [12, 13]. In the context of nicotine addiction and its neurobiological mechanisms, the nAChRs of most relevance are those expressed in the brain, attributable to their proposed role in the neuromodulation of several CNS transmitters [14], as described below.

Nicotinic acetylcholine receptors in the brain, located primarily on presynaptic terminals [14] and to a lesser extent at somatodendritic, axonal, and postsynaptic locations (for review, see [15]), are diverse members of the neurotransmitter-gated ion channel superfamily [16] comprised of five nAChR subunits (i.e., α and β subunits combined or α subunits alone) that combine to form a functional receptor [8, 16–18]. The nAChRs expressed most widely in the brain are comprised of α_4 , β_2 , or α_7 subunits [11, 17]; nicotine-induced dopamine release is dependent on the β_2 subunit [19]. Importantly, the way in which individual subunits (α_1 to α_{10} ; β_1 to β_4 [11, 18, 20]) combine to form a nAChR influences its affinity for nicotine binding [11, 16]. For instance, nAChRs formed in a heteropentameric configuration comprised of α and β subunits, which contain β_2 subunits, have a high affinity while nAChRs formed in a homopentameric configuration comprised only of α_7 subunits have a low affinity [16]; among nAChR subunits, β_2 has the highest affinity for nicotine [21].

Activation of nAChRs in the brain releases multiple neurotransmitters, including dopamine (DA), serotonin (5-HT), glutamate (Glu), γ -aminobutyric acid (GABA), and endogenous opioid peptides (EOPs) [16]. These neurotransmitters are associated with nicotine’s reinforcement, dependence and tolerance, and withdrawal, as described below.

15.2.3 Nicotine Reinforcement Neurosubstrates

In the context of substance abuse, nicotine has been known for decades to be dependence producing [22]; nicotine dependence diagnostic criteria have been defined

elsewhere [2]. Nicotine's dependence-producing properties are, in part, due to its pharmacodynamic profile. Nicotine serves as an effective reinforcer in humans and in several species of animals, including rats, mice, and nonhuman primates, as demonstrated by self-administration studies [23, 24]. In humans, nicotine's reinforcing effects include mild euphoria [25], increased energy and arousal, and decreased stress and anxiety and appetite [26]. Recent studies of the trajectory of patterns of acquisition of nicotine self-administration in rats may serve as a bridge to human longitudinal work. For instance, studies by Lanza et al. [27] and Donny et al. [28] demonstrate that individual differences appearing early in the acquisition process affect resulting patterns of nicotine self-administration, which is consistent with findings that individual differences in early tobacco use may influence differentially the development of regular tobacco use and the emergence of dependence in humans [29].

Neurosubstrates involved in nicotine reinforcement include the mesolimbic dopaminergic system (for reviews, see [11, 30]) and the following neurotransmitters: DA, Glu, and GABA [8]. Other neurosubstrates involved include corticotropin-releasing factor (CRF) and opioid receptors [8]. The role(s) of each neurosubstrate in the modulation of nicotine reinforcement has been provided below.

Acute nicotine administration, possibly by activating nAChRs on mesolimbic dopaminergic neurons at the ventral tegmental area (VTA) and nucleus accumbens [31], increases the firing rate of VTA dopaminergic neurons [32] and elevates dialysate DA levels specifically in the nucleus accumbens shell [33–36]. A series of studies by Nisell et al. [36–38] have demonstrated that nAChRs in the VTA, compared to those in the nucleus accumbens, have a more salient role in mediating the effects of nicotine on DA release. Further evidence of the role of nAChRs on VTA dopaminergic neurons in nicotine reinforcement has been provided by findings that injections of dihydro- β -erythroidine, a nicotinic antagonist, into the VTA [39], microfusion of 6-hydroxydopamine into the nucleus accumbens, producing mesolimbic dopamine system lesions [40], and administration of DA receptor antagonists (SCH23390 and spiperone) [41] decrease nicotine self-administration. These findings are specific to nicotine's reinforcing effects, as opposed to other potential nicotine-induced effects (cognitive improvement) [42].

Another neurosubstrate that may mediate nicotine reinforcement is the Glu neurotransmitter system [8]. Nicotine may elevate striatal DA levels either directly, by glutamatergic stimulation of the ventral striatum, and/or indirectly, by glutamatergic stimulation of VTA dopaminergic neurons projecting to the striatum [8]. By activating excitatory presynaptic nAChRs on glutamatergic terminals, nicotine increases glutamate release [43, 44]. As in other brain sites, acute nicotine administration increases Glu release in the VTA [45]. Within the VTA, nicotine is thought to act at presynaptic α_7 nAChRs located on Glu afferents [45], whereby increasing Glu release, which in turn stimulates DA release in the nucleus accumbens [45–47]; multiple studies suggest α_7 nAChR subunits and/or $\alpha_4\beta_2$ nAChR subtypes have a role in nicotine reinforcement, DA release, and the anxiolytic effects [19–50] that contribute to continued tobacco use [22] (alternatively, see [51]). As an intermediary step, the enhanced Glu release acts at *N*-methyl-D-aspartate (NMDA) and non-NMDA receptor sites on postsynaptic dopaminergic neurons, which increases their firing rate [8]. Blockade of metabotropic glutamate receptor 5, using the mGluR5 antagonist 2-methyl-6(phenylethynyl)-pyridine, decreases nicotine self-administration in rats and mice, potentially by decreasing nicotine-stimulated DA release in the mesolimbic system [52].

Another neurosubstrate that may mediate nicotine reinforcement is the GABA neurotransmitter system [8]. Dopaminergic neurons projecting from the VTA to the nucleus accumbens [53] receive descending GABAergic input from the ventral pallidum and the nucleus accumbens [54, 55]. Dopaminergic tone in the VTA and nucleus accumbens is inhibited by these GABAergic neurons [11, 56]. At the VTA, DA inhibition involves GABAergic inhibitory afferents to dopaminergic ventral tegmental neurons [54, 57] and interneurons within the VTA [58]. In the nucleus accumbens, DA inhibition involves medium spiny GABA neurons [58]. Demonstrative of GABA's neuromodulation effects, administration of γ -vinyl-GABA (GVG, or vigabatrin), an irreversible GABA transaminase inhibitor [59], abolishes expression and acquisition of conditioned place preference, nicotine-induced increases in synaptic DA [60], and dose dependently decreases nicotine self-administration in rats [59]. Additionally, administration of baclofen or CGP44532, selective GABA_B agonists, decreases nicotine self-administration [61–63], suggesting that enhancement of GABA transmission via GABA_B receptors may antagonize nicotine's reinforcing effects. Baclofen's effects on tobacco smoking has been examined in only one clinical study [64]. Acute administration of baclofen was not demonstrably efficacious in reducing cigarette smoking or nicotine-craving ratings.

Other neurosubstrates that may mediate nicotine reinforcement involve the hypothalamic–pituitary–adrenal (HPA) axis and corticotropin-releasing factor [8] (CRF; also abbreviated CRH, for corticotropin-releasing hormone [65]), a neuropeptide neurotransmitter involved in stress responses [65]. Corticotropin-releasing factor transmission in the paraventricular nucleus of the hypothalamus (PVN) has been hypothesized to mediate the effects of acute nicotine exposure on the HPA in rodents and humans [8]. In rats, injection of nicotine or exposure to cigarette smoke increases corticosterone and adrenocorticotrophic hormone (ACTH) levels [66, 67]. A series of studies by Matta et al. (1987) [68] suggest these effects are mediated by central nicotinic cholinergic receptors. Several findings indicate that CRF in the paraventricular nucleus mediates the effects of nicotine on the HPA stress response system. First, nicotine stimulates CRF release in vitro from the rat hypothalamus [69]. Second, nicotine produces concentration- and time-dependent increases in CRF messenger RNA expression in the AR-5 immortalized amygdalar cell line [70]. Third, CRF-containing synaptic vesicles are located in axon terminals with nAChRs in the rat hypothalamus (i.e., median eminence), indicating that nicotine may act on nAChRs in axon terminals to release CRF [71]. Lastly, nicotine administration induces dose-dependent cFOS expression in CRH-containing regions of the PVN [72], bed nucleus of the stria terminalis and central nucleus of the amygdala, and dorsal raphe [73].

In humans, cigarette smoking or nicotine infusions (i.e., intravenous administration), under limited conditions, increases cortisol and ACTH levels [74–78]. One study [77] demonstrates that within a 10-min smoking period smoking two conventional (2-mg nicotine) cigarettes compared to two very low nicotine (0.2-mg nicotine) cigarettes increases cortisol levels. Another study [78], using controlled smoking procedures (e.g., interpuff interval of 25 s), demonstrates that within a 12-min smoking period 24 puffs (equivalent of two cigarettes, approximately) of high-nicotine (15.48 mg nicotine; [79]) cigarettes, but not low-nicotine (1.1-mg nicotine, as determined by the manufacturer, Murty Pharmaceuticals Inc.) cigarettes, increases ACTH levels. A third study [75], having similar design features as those above,

reveals a comparable pattern of results for both cortisol and ACTH levels. Like findings have been reported elsewhere [80]. In nonsmoking, nicotine-naïve subjects receiving intravenous nicotine bitartrate (0.25 and 0.5 µg/kg/min), only infusions of the 0.5-µg dose increase cortisol and ACTH levels [76].

Overall, the relationship between the HPA axis/hormones and abuse-related effects of drugs is not understood fully [78]. However, HPA axis activation is believed to be involved in several phases of the addiction process [78]. Multiple hypotheses regarding the involvement of the HPA axis/hormones have been raised. One hypothesis, using cocaine as a comparator, posits that ACTH and cortisol may contribute to nicotine's reinforcing effects [78]. Another hypothesis proposes that CRH may play a role in mediating nicotine's effects on behaviors pertaining to stress and anxiety [8], generally, and the anxiety and irritability often associated with nicotine withdrawal, specifically [11, 78], as described below (Section 15.2.5).

The final neurosubstrate presented in this chapter that may mediate nicotine reinforcement involves opioid receptors. Two primary lines of evidence suggest opioid receptors at least partially mediate nicotine reinforcement. First, nicotine influences the release of EOPs [81, 82], both within and outside the mesolimbic DA system [11]. Within the mesolimbic DA system, nicotine increases tissue levels of opioid peptides in the nucleus accumbens [83, 84], which contain a high density of µ-opioid receptors [85]. These receptors have been hypothesized to be occupied by endogenous opioid ligands released by nicotine [86]. Outside the mesolimbic DA system, nicotine induces the release of the pro-opiomelanocortin peptide group by stimulating nAChRs within the hypothalamus; the pro-opiomelanocortin peptide group includes the precursor β-endorphin [11, 87] which, while undetermined, may be involved in mediating nicotine's positive reinforcing effects [11]. Taken together, nicotine's positive reinforcing effects may be mediated by activation of enkephalin neurons (i.e., dopamine-independent reward systems) [11]. Second, opioid receptor antagonists such as naloxone and naltrexone have demonstrable efficacy in decreasing cigarette consumption and self-reported smoking satisfaction and increasing smoking cessation rates [88–91], suggesting that opioid receptors may modulate nicotine's reinforcing effects [8] (alternatively see [92, 93]).

15.2.4 nAChR Functional Adaptations

Features common among drugs of abuse are their ability to produce and maintain dependence and tolerance [2]. For nicotine, both dependence and tolerance may involve functional adaptations of nAChRs [8, 11, 18, 94], as described below. Contrary to most agonists, which downregulate receptors with chronic drug exposure [94], chronic nicotine administration desensitizes and inactivates nAChRs, which leads paradoxically to an upregulation of nAChR sites [8, 94, 95]. This nicotine-induced, paradoxical upregulation of nAChRs has been observed in the rodent brain [96, 97], human brain [98–100], and human blood leukocytes [101] and is dose dependent [99, 101].

The role of nAChR desensitization and upregulation in the subjective effects of acute nicotine exposure and in the development and maintenance of nicotine dependence has undergone much speculation [102, 103]. Experimental findings pertaining to the effects of chronic nicotine exposure on nAChRs in animals have been mixed. For instance, there is some evidence that chronic nicotine exposure

increases nAChR numbers [104, 105] and function [106]. Conversely, there is some evidence that chronic nicotine exposure decreases nAChR numbers [107] and function [108]. Behaviorally, as a means of counteracting the continuous agonist actions of nicotine on the receptors, nicotine dependence is related to the decrease in nAChR numbers and/or function [8, 109]. In turn, the prolonged functional desensitization or inactivation of nAChRs associated with chronic nicotine administration has been hypothesized to lead to receptor upregulation [107, 110, 111] (alternatively, see [112]). Importantly, because the majority of studies indicating nAChR changes have been conducted *in vitro*, the functional significance of these changes *in vivo* is unknown [103] and thus requires further study [113]. Also worth noting, particularly when interpreting seemingly opposite effects, is that different nAChR subtypes vary in their sensitivity to nicotine, as evidenced by differential degrees and rates of desensitization and upregulation [8, 11]. For instance, nAChRs composed of $\alpha_4\beta_2$ subunits desensitize slowly [18] while α_7 receptors desensitize rapidly [18]. Thus behavioral observations may reflect the combined effects of complex adaptations of different nAChR types [8].

It appears plausible that initial discomfort associated with smoking cessation reflects the 300 to 400% increase in nicotine receptors [100], many of which are abruptly unoccupied. In turn, nicotine replacement therapy (NRT) may provide its benefits, in part, by occupying these receptors, thus contributing to stable physiological functioning while the person behaviorally adapts to living without smoking. The therapy, in turn, provides a means to reduce gradually daily nicotine over several weeks or months, potentially, allowing receptor levels to achieve an appropriate balance. The question of returning to “baseline” or “normal” receptor levels may not be meaningful for tobacco users because they typically began smoking during adolescence with long term cessation achieved (if it is achieved) after several decades of tobacco use. The possibility that some tobacco users will require long-term NRT use (or other therapeutic measures) to sustain tobacco-delivered nicotine abstinence is then not surprising.

The aforementioned nAChR adaptations likely are involved in producing tolerance to some of nicotine’s acute effects [114]. Tolerance to nicotine’s acute effects is gained throughout the day, with repeated acute nicotine exposure, and lost throughout the night, due to overnight abstinence while the smoker sleeps [115]. The time course of tolerance, whether a gain or loss, varies across nicotine-induced responses [114, 116, 117]. For instance, smokers develop a large degree of tolerance to nicotine’s acute subjective and cardiovascular effects [114, 118–120].

15.2.5 Nicotine Withdrawal Neurosubstrates

As with many other drugs of abuse, nicotine, upon abrupt cessation (i.e., smoking abstinence in humans), can produce an aversive withdrawal syndrome in humans [121, 122] and rodents, though observed less reliably in mice [109, 123–127]. The nicotine withdrawal syndrome, as defined by the APA [2], consists of subjective, cognitive, and physiological components and has been cited by many smokers as a reason for failed quit attempts [128], which results in continued tobacco use. Common subjective effects include restlessness, impatience, irritability, depressed mood, dysphoria, craving, and anxiety [2, 121, 129]. A common cognitive effect includes difficulty concentrating [2, 121, 129]. Common physiological effects include

decreases in heart rate and adrenaline and noradrenaline excretion and increases in skin temperature, electroencephalographic theta power, and weight [130–133]. In rats, the most prominent signs of withdrawal include abdominal constrictions (writhes), gasps, ptosis, facial fasciculation, and eyeblinks [124, 134, 135]. These withdrawal signs are mediated both centrally and peripherally [11, 124, 136]. Other withdrawal signs observed in rodents include disruptions of food-maintained learned behaviors in rats [137], increases in the acoustic startle response in rats [138], decreases in prepulse inhibition in mice [127], and elevations in brain reward thresholds [109, 135, 139]. Several dissociations between threshold elevations and somatic signs [134, 139] suggest that the various components of nicotine withdrawal are mediated by different substrates [8]. Neurosubstrates involved in nicotine withdrawal, comprised of many of the same substrates involved in nicotine reinforcement, include the mesolimbic dopaminergic system and the following neurotransmitters: DA, 5-HT, and Glu [8]. Other neurosubstrates involved include CRF and opioid receptors [8]. The role(s) of each neurosubstrate in nicotine withdrawal has been provided below.

Precipitated nicotine withdrawal, as induced by systemic or intra-VTA mecamylamine (nAChR antagonist) administration, decreases DA dialysate levels in the nucleus accumbens [140, 141] and the central nucleus of the amygdala [142] in nicotine-treated rats. Additionally, mecamylamine injections into the VTA dose dependently precipitates a constellation of somatic withdrawal signs [143], suggesting possibly that nAChR transmission in the VTA has a role in the expression of nicotine withdrawal's somatic signs [8]. Similar decreases in DA levels in the nucleus accumbens have been observed with withdrawal from other drugs of abuse, including ethanol, morphine, cocaine, and amphetamine [144, 145]. Further demonstrative of the involvement of DA in nicotine withdrawal is the finding that bupropion (Zyban), a smoking cessation aid that acts, in part, by inhibiting neuronal reuptake of DA, enhances DA transmission [146, 147]. Moreover, while its effects on nicotine self-administration have been varied [148–150], bupropion has been shown to reverse threshold elevations and somatic signs associated with nicotine withdrawal [135, 151].

Because administration of nAChR antagonists into the VTA decreases nucleus accumbens dialysate levels, as described above, suggests that reductions in endogenous cholinergic tone may cause nicotine withdrawal. The receptors involved most likely are α_4 -containing high-affinity nAChRs [152].

Another neurosubstrate that may mediate nicotine withdrawal involves the 5-HT neurotransmitter, generally, and the 5-HT_{1A} receptor, specifically [153, 154]. Pre-treatment with 8-OH-DPAT and LY274600, 5-HT_{1A} receptor agonists, enhance the auditory startle response observed during nicotine withdrawal, whereas NAN-190, WAY-100635, or LY206130, 5-HT_{1A} receptor antagonists, blocks the increase in startle response [155]. Additionally, during nicotine withdrawal, the sensitivity of dorsal raphe nucleus neurons to 8-OH-DPAT increases [156]. Therefore, nicotine withdrawal, by increasing potentially the inhibitory influence of somatodendritic 5-HT_{1A} autoreceptors located within the raphe nuclei, may decrease 5-HT release into forebrain and limbic brain sites [157, 158]. Evidence of this is provided by the finding that, in rats undergoing nicotine withdrawal, coadministration of fluoxetine, a serotonin-selective reuptake inhibitor, and p-MPPI, a 5-HT_{1A} receptor antagonist, reverses elevation of brain reward thresholds but not somatic signs [139], lending further support that nicotine withdrawal's affective and somatic components are not

mediated by the same mechanism [8]. Consistent with the overall findings above, buspirone, a partial 5-HT_{1A} agonist, demonstrates efficacy in smoking cessation trials and may alleviate withdrawal severity, at least among short-term symptoms, in abstinent smokers [159–161] (alternatively, see [162]).

Another neurosubstrate that may mediate nicotine withdrawal [8], particularly in light of its role in nicotine reinforcement (Section 15.2.3), is the Glu neurotransmitter system. Because Glu neurotransmission stimulates DA release [45, 47], there is reason to believe that decreases in Glu transmission may have a role in mediating nicotine withdrawal. Contrary to expectation, this hypothesis is not supported empirically. For instance, LY354740, a Glu analog with agonist activity at Group II metabotropic glutamate receptors (mGluRs), dose dependently attenuates enhanced auditory startle responding in rats undergoing nicotine withdrawal [138], suggesting that enhanced Glu transmission is involved, at least with this aspect of nicotine withdrawal [8]. Further investigation in different brain sites is necessary to determine the role of Glu in nicotine withdrawal [8].

Other neurosubstrates that may mediate nicotine withdrawal involve the CRF system and the HPA axis [8]. Cigarette smoking elevates salivary cortisol levels in habitual smokers [163]. During short-term tobacco abstinence, cortisol levels remain virtually unchanged [164]. However, during long-term tobacco abstinence, cortisol levels decrease [165, 166]. There is rapid tolerance to nicotine's effects on plasma corticosterone [158]. The effects of nicotine withdrawal on corticosterone levels are mixed. There is evidence that nicotine withdrawal increases, decreases, or has no effect on corticosterone levels [157, 167, 168]. Further study is necessary to characterize more fully the effects of nicotine withdrawal on CRF transmission and HPA axis function [8].

The final neurosubstrate presented in this chapter that may mediate nicotine withdrawal involves opioid receptors [8]. There is evidence that naloxone, an opiate antagonist, precipitates an abstinence syndrome in nicotine-dependent rats [169]. In a related experiment, morphine, an opioid receptor agonist, reverses signs of spontaneous nicotine withdrawal [169]. Another study demonstrates that nicotine attenuates naloxone-induced jumping behavior in morphine-dependent rats [170]. Taken together, these findings suggest that common neurobiological substrates may mediate nicotine and opiate withdrawal. Findings from another study [134] reveal that, while only high naloxone doses precipitate threshold elevations and somatic signs in nicotine-treated rats, comparably lower doses induce conditioned place aversions. These results indicate that, while brain reward thresholds and somatic withdrawal signs may not be sensitive to alterations in opioid transmission, conditioned motivational states may be [8]. Moreover, findings that naltrexone and naloxone antagonize nAChRs suggest that opioid receptor antagonists may precipitate nicotine withdrawal [171], at least in part, by blocking nAChRs directly [8].

15.2.6 Pharmacokinetics

Pharmacokinetics concerns the absorption, distribution, and metabolism and elimination of a drug. This section addresses each of these areas as it pertains to nicotine, covering a range of nicotine-delivering tobacco products, as described below.

15.2.6.1 Absorption. When delivered by tobacco smoke inhalation, nicotine is carried on tar droplets as part of a complex aerosol that is inhaled into the lung. There, particles are deposited in small airways and alveoli, where nicotine is rapidly absorbed. Venous blood concentrations of nicotine rise rapidly during cigarette smoking and peak at its completion [172]. During smoking, levels of nicotine in arterial blood can more than double the levels observed in venous blood [173]. Presumably, the rapid absorption of nicotine from cigarette smoke through the lung is the result of the huge surface area of the alveoli and the dissolution of nicotine into fluid of physiological pH, which facilitates transfer across cell membranes [174].

Nicotine from chewing tobacco, snuff, and oral nicotine replacement medications (i.e., gum, lozenge, and inhaler) is absorbed through the oral mucosa. The absorption of nicotine across biological membranes depends upon the pH. The pK_a of nicotine is about 8, meaning that 50% of the nicotine is absorbed in a solution with a pH of 8. The pH of smoke from flue-cured tobaccos found in most cigarettes is acidic; thus very little of the nicotine from tobacco smoke is absorbed in the mouth. In contrast, chewing tobacco and snuff are buffered to an alkaline pH to facilitate the absorption of nicotine through the mucosal membranes [175]. Venous plasma nicotine concentrations rise fairly rapidly and reach concentrations comparable to those seen during cigarette smoking or even higher, peaking about 10–20 min after the product is removed from the mouth [176].

The pH of smoke from large cigars and pipes is somewhat alkaline; thus nicotine in the smoke of these products can be absorbed through the oral mucosa or the lung [177]. In addition, the whole tobacco aqueous pH in large cigars is alkaline, suggesting that nicotine can be absorbed into the oral mucosa directly from the cigar when the cigar is held in the mouth [177]. In contrast, the pH of the whole tobacco aqueous pH of small cigars is acidic, like a cigarette [177]. Thus, little nicotine from small cigars would be absorbed through the oral mucosa; however, like a cigarette, nicotine would readily be absorbed into the lung if the smoker inhales.

15.2.6.2 Distribution. After absorption into the blood, nicotine is distributed extensively to body tissues with a steady-state volume of distribution averaging 180 L. Based upon animal research at steady-state nicotine concentrations, spleen, liver, lungs, and brain have a high affinity for nicotine, whereas the affinity of adipose tissue is relatively low [119]. After rapid intravenous injection, concentrations of nicotine decline rapidly because of tissue uptake of the drug. Shortly after injection, concentrations in arterial blood, lung, and brain are high, while concentrations in muscle and adipose tissues are low [119]. Uptake into the brain occurs within 1–2 min, and blood levels fall because of peripheral tissue uptake for 20 or 30 min after administration. Thereafter, blood concentrations decline more slowly, as determined by rates of elimination and rates of distribution out of storage tissues [119].

Nicotine inhaled in tobacco smoke enters the brain almost as quickly as after rapid intravenous injection. Because of the delivery into the lung, peak nicotine levels in the brain may be higher, and the lag time between smoking and entry into the brain shorter than after intravenous injection [119]. The distribution half-life, which describes the movement of nicotine from the blood and other rapidly perfused tissues, such as the brain and other body tissues, is about 9 min [178], whereas the elimination half-life of nicotine is about 2 h. Distribution kinetics determine the time course of CNS actions of nicotine after smoking a single cigarette.

15.2.6.3 Metabolism and Elimination. Nicotine is rapidly and extensively metabolized, primarily in the liver but also to a small extent in the lung [119]. Nicotine's primary metabolites are cotinine and nicotine-*N*-oxide, neither of which appears to be pharmacologically active [174]. The half-life of nicotine averages about 2 h, although there is considerable variability, generally ranging from 1 to 4 h [179]. The half-life of cotinine is much longer (16–20 h), making it a much better marker of nicotine intake than nicotine itself [180]. There is evidence that mentholated cigarette smoking significantly inhibits the metabolism of nicotine, suggesting that mentholated cigarette smoking enhances systemic nicotine exposure [181]. Inhibition of nicotine metabolism occurs both by slower oxidative metabolism to cotinine and by slower glucuronide conjugation. The level of renal excretion depends on urinary pH and urine flow and accounts for 2–35% of total elimination [182].

As reviewed by Henningfield and Benowitz [3], genetic variations can affect nicotine metabolism. Specifically, the cytochrome CYP2A6 enzyme is the liver enzyme largely responsible for the metabolism of nicotine to cotinine, and difference in the expression of this enzyme can have dramatic effects on metabolism. For example, in a study of human liver microsomes, pretreatment with coumarin, a specific and selective CYP2A6 substrate, competitively inhibited cotinine formation by 85% [183]. Genetic variations that alter nicotine metabolism can affect smoking behavior. Tyndale and Sellers [184] found that there was an underrepresentation of individuals carrying defective *CYP2A6* alleles in a tobacco-dependent population and that, among smokers, those with deficient nicotine metabolism smoked fewer cigarettes. Further, inhibition of the CYP2A6 enzyme increases nicotine bioavailability by decreasing first-pass metabolism and decreases smoking [185].

15.3 PHARMACOLOGICAL TREATMENT OF NICOTINE DEPENDENCE AND WITHDRAWAL

15.3.1 Overview

Knowing that cigarette smoking has a pathophysiological basis, as evidenced by the role neurobiological mechanisms have in nicotine reinforcement and dependence, tolerance, and withdrawal, as discussed above, underscores the importance of understanding better nicotine pharmacology and the pharmacotherapies used in the treatment of nicotine dependence (i.e., known vernacularly as nicotine addiction), the foci of the chapter.

As discussed elsewhere, two distinct but typically interrelated disorders comprise what is commonly referred to as nicotine addiction: nicotine dependence and nicotine withdrawal [186]. Nicotine dependence refers to the chronic, relapsing pattern of tobacco use driven strongly by nicotine administration, whereas nicotine withdrawal is the syndrome of signs and symptoms that begin to emerge within a few hours of discontinuation of nicotine intake. Diagnostic criteria for each are provided by the APA [2] and WHO [1]. The most widely recognized goal of therapy is to help the tobacco user achieve and sustain abstinence by treatment of dependence and withdrawal [187–189]. In principle, other goals, such as temporary reduction of withdrawal symptoms to sustain temporary abstinence (e.g., in smoke-free settings) and partial nicotine replacement to enable sustained smoking reduction (i.e., “harm reduction”), are viable and have been discussed elsewhere more recently [190, 191].

As noted in Section 15.2, there are a number of neural mechanisms by which a medication may alleviate withdrawal symptoms, simulate some of nicotine's reinforcing effects, or block nicotine's reinforcing effects. These have led to the postulation of a variety of potential medications for treating tobacco dependence and/or withdrawal, as have been discussed elsewhere [187, 192]. However, the most effective and widely used medications are nicotine replacement medications and other medications that alter the reinforcing effects of nicotine.

As reviewed in Section 15.2, many of the effects of nicotine in the brain are likely to be mediated through neuromodulation in which nicotine potentiates the release of neurotransmitters, including DA, Glu, GABA, and 5-HT. By selectively activating or blocking these neurotransmitters, one might be able to mimic or block some of the reinforcing effects of nicotine.

The following sections review the available pharmacological therapies for smoking cessation and discuss potential targets for the development of new medications.

15.3.2 Nicotine Replacement Medications

The most direct way to help people manage the symptoms of nicotine dependence and withdrawal is therapeutic use of nicotine replacement medications (NRTs) [193–195] to at least partially substitute for the effects of tobacco self-administration. Nicotine medications make it easier to abstain from tobacco by replacing, at least partially, the nicotine formerly obtained from tobacco, thereby providing nicotine-mediated neuropharmacological effects. These neuropharmacological effects include increased expression and reduced turnover of nicotine receptors in the brain and other parts of the body, alteration of brain electroencephalography and regional cerebral glucose metabolism, and activation of dopaminergic reinforcement systems in the brain [196]. Nicotine is the most important substance in tobacco in that it causes and sustains addiction to tobacco. However, a variety of other substances with their own direct pharmacological actions, in interaction with nicotine, and by modulation of sensory effects undoubtedly contribute to the overall addicting effects of tobacco smoke [119, 197–200]. The importance of other substances has not been fully elucidated, but their role may be one factor limiting the effectiveness of NRT.

Laboratory research has demonstrated that animals [201] and humans [202] who have been chronically exposed to nicotine or tobacco smoke will self-administer nicotine infusions. Nicotine administration has been shown to reverse the nicotine withdrawal seen upon discontinuation of chronic nicotine exposure in rats [123] and humans [203, 204].

Currently approved NRT products include the transdermal nicotine patch and several acute NRT products, including nicotine gum, lozenge, sublingual tablet, vapor inhaler, and nasal spray. The differences in the pharmacokinetic profile of these products are illustrated in Figure 15.1.

15.3.2.1 Transdermal Nicotine Patch. Nicotine patches are applied to the skin once a day and deliver nicotine through the skin at a relatively steady rate. Use of transdermal nicotine reduces the symptoms of nicotine withdrawal, including tobacco craving [187, 194]. The nicotine patch has been shown to reduce background craving compared to placebo; however, in contrast to acute NRT formulations, the

Figure 15.1 Venous blood concentrations in nanograms of nicotine per millimeter of blood as a function of time for various nicotine delivery systems. Data on nasal spray are from Schneider et al. [215]; data on gum are from Benowitz et al. [172]; data on patch are from Benowitz [204a]; data on sublingual tablet are from Molander and Lunell [212]; data on lozenge are from Choi et al. [211]; data on inhaler are from Schneider et al. [204b]; and are based on 80 puffs in 20 min, a dosing regimen not typical of clinical use.

nicotine patch has a weaker effect on craving associated with exposure to a provocative stimulus [205, 206].

Chronic nicotine also may reduce the effects of subsequent nicotine delivery, which might decrease the likelihood that a lapse will result in a complete return to smoking (relapse). For example, a study of cigarette smoking stimulant abusers indicates that nicotine patches produce tolerance to the effects of intravenous nicotine [207]. Under a placebo maintenance condition, intravenous nicotine produces robust dose-related subjective effects, with maximal increases similar to the high dose of cocaine; however, nicotine maintenance significantly decreases the subjective and reinforcing effects of intravenous nicotine. Nicotine patches do not alter responses to cocaine or caffeine.

There are currently four patch formulations on the market, varying widely in their design, pharmacokinetics, and duration of wear (i.e., 24- and 16-h wear). The diversity in patch systems has been described in reviews [194, 208], and the differences in pharmacokinetics have been illustrated in a head-to-head clinical trial [209]. All of the patch types are available in a range of dosages, and progressively lower doses are used to provide weaning over a period of several weeks or longer to enable gradual adjustment of their bodies to lower nicotine levels and ultimately to a nicotine-free state. Some formulations and indications also provide for less dependent smokers to use a lower dose.

15.3.2.2 Acute Delivery Systems. There are several options available to smokers that, unlike the nicotine patch, allow them to self-administer a dose of nicotine on an “as-needed” basis. These include nicotine gum, lozenge, sublingual tablet, oral inhaler, and nasal spray. All of these products except the nasal spray deliver nicotine through the oral mucosa. Acute-dosing products have the benefit that both the amount and timing of doses can be titrated by the user. Thus, smokers with more

nicotine tolerance or greater need can get a higher nicotine dose, and smokers who are experiencing acute adverse effects can scale back their intake.

Nicotine gum is available in two doses: 2 and 4 mg, delivering approximately 1 and 2 mg, respectively [210]. A 1-mg lozenge has been available in some European countries for some time; however, no efficacy data are available, and the efficacy of this low dose is in question. A newer nicotine lozenge, available in 2- and 4-mg formulations, has been approved in the United States, Europe, and Australia. Single-dose studies demonstrate 8–10% higher maximum concentration (C_{\max}) and 25–27% higher area-under-the-curve ($AUC_{0-\infty}$) values from lozenges compared to gums at both 2- and 4-mg dose levels, which is probably due to the residual nicotine retained in the gum [211]. A small sublingual nicotine tablet has been developed and is currently being marketed in many European countries but is not yet available in the United States. The product is designed to be held under the tongue, where the nicotine is absorbed sublingually over about 30 min. The product that is currently available contains 2 mg nicotine, and the levels of nicotine obtained by use of the 2-mg tablet and 2-mg nicotine gum are similar [212]. The nicotine vapor inhaler consists of a mouthpiece and a plastic cartridge containing nicotine. When the inhaler is “puffed,” nicotine is drawn through the mouthpiece into the mouth of the smoker. Each inhaler cartridge contains 10 mg nicotine, of which 4 mg can be delivered and 2 mg is absorbed with intensive use [213]. The product does not deliver nicotine to the bronchi or lungs, but rather its nicotine is deposited and absorbed primarily in the mouth, much like nicotine gum [214]. The nasal spray was designed to deliver doses of nicotine to the smoker more rapidly than other NRT products. The device is a multidose bottle with a pump that delivers 0.5 mg of nicotine per 50- μ L squirt. Each dose consists of two squirts, one to each nostril. Nicotine from the nasal spray is absorbed into the blood more rapidly than from gum [215].

As shown in Figure 15.1, nicotine delivery from these acute NRT formulations is faster than transdermal delivery. However, there remains a vast difference in the pharmacokinetic profiles of cigarettes and NRT products. Even nicotine nasal spray, which produces measurably faster increases in venous blood nicotine levels compared to other oral NRT formulations, does not equal the venous levels produced by cigarettes. Even more importantly, none of the currently available formulations produces the spikes in arterial blood, the blood levels that actually enter the brain. A study by Henningfield et al. (1993) demonstrates that the arterial levels achieved by smoking are much higher than levels seen in venous blood, and the nicotine may reach the brain even faster after smoking than after intravenous dosing [173]. Speed of delivery has been shown to influence nicotine’s effects in both animals and humans [173, 216].

15.3.3 Nicotinic Pharmacotherapies

15.3.3.1 Nicotinic Partial Agonists. A partial agonist is a compound that, even at high doses, does not produce the same response as a full agonist. Because there is a ceiling on the effects of a partial agonist, it is plausible that a partial nicotine agonist would have a lower risk of adverse events and have a lower abuse potential than a medication containing nicotine. A variety of nAChR subtypes have been identified with distinct structural and functional properties. The subtype that has generally been identified as being associated with the addictive effects of nicotine is the $\alpha_4\beta_2$. It is plausible that a compound that binds with a high degree of specificity or with a

greater affinity to this subtype relative to nicotine will have a higher level of safety and possibly a higher level of efficacy. However, to the extent that other subtypes might be associated with these effects, the efficacy could be muted compared to nicotine, which is less specific.

One such compound that received FDA approval in 2006 and is available as a prescription smoking cessation aid is varenicline, a nicotine partial agonist that is specific to the $\alpha_4\beta_2$ (nicotinic) receptor. Clinical trials of varenicline suggest that the medication is efficacious for smoking cessation and is safe.

15.3.3.2 Nicotinic Antagonists. In theory, a nicotinic antagonist would block the effects of cigarette smoking, which would subsequently decrease the reinforcing value of smoking, which in turn would lead to extinction of the behavior. Mecamylamine is a noncompetitive antagonist at the nAChR site. Mecamylamine increases ad libitum smoking behavior when administered alone and also attenuates smoking satisfaction as well as many of the physiological, behavioral, and reinforcing effects of nicotine [217]. There is some evidence that mecamylamine may be useful for some recalcitrant smokers as a smoking cessation aid [218]. However, the side effects of the medication (hypotension and constipation) may limit its utility.

Mecamylamine in combination with nicotine transdermal medication may produce better cessation outcomes than nicotine alone. For example, a randomized, double-blind, placebo-controlled clinical trial reveals that a combination of the nicotine patch plus mecamylamine produces abstinence rates three times higher than those for nicotine patch alone [219]. Mecamylamine also significantly reduces cigarette craving, negative affect, and appetite. Side effects such as constipation and dizziness, however, remain common. These results suggest that mecamylamine combined with nicotine replacement may ultimately prove to be a useful aid in smoking cessation.

15.3.4 Nonnicotinic Pharmacotherapies

Nonnicotine pharmacotherapies for smoking cessation have been extensively reviewed elsewhere [192, 220]. As previously mentioned, many of the effects of nicotine in the brain are likely to be mediated through neuromodulation in which nicotine potentiates the release of DA and 5-HT [221]. By selectively activating these neurotransmitters, one might be able to mimic some of the reinforcing effects of nicotine.

15.3.4.1 Bupropion. Bupropion is an atypical antidepressant drug that is the only non-nicotine-based prescription medicine approved for smoking cessation by the Food and Drug Administration (FDA). Its mechanism of action is presumed to be mediated by its capacity to block neuronal reuptake of DA and/or norepinephrine [187]. Relative to other antidepressants, bupropion has a relatively high affinity for the DA transporter [222].

Animal studies demonstrate that bupropion alters the reinforcing and withdrawal effects of nicotine. One study indicates that low doses of bupropion reduce the rewarding effects of nicotine and the affective and somatic symptoms of withdrawal [135]. Another study examined the effects of bupropion (5–40 mg/kg) on the reinforcing properties of nicotine and food in rats under two different schedules of

reinforcement [150]. The authors report that pretreatment with the highest dose of bupropion (40 mg/kg) results in a 50% reduction of nicotine intake in rats self-administering 0.03 mg/kg/infusion of nicotine under a fixed-ratio (FR) schedule. However, pretreatment with bupropion does not affect the self-administration of nicotine under a progressive-ratio (PR) schedule. These findings are challenging to interpret but may indicate that a high dose of bupropion decreases the reinforcing properties of nicotine under conditions where doses can be obtained at regular and relatively short intervals, while leaving intact the motivation to work for nicotine when doses are more widely spaced. Taken together, these results suggest that bupropion has several actions demonstrated in animals that could explain its ability to increase rates of cessation in humans.

15.3.4.2 Tricyclic Antidepressants. Tricyclic antidepressants have a relatively high affinity for both 5-HT and 5-HT transporters and some affinity for the DA transporter [222]. Several clinical trials have demonstrated the potential efficacy of nortriptyline for smoking cessation in smokers without history of major depression [223] or with such history [224], and nortriptyline has been listed by the Agency for Health Research Quality as a second-line therapy [187]. The tricyclic antidepressant doxepin has also been shown in a small human study to improve cessation rates [225]; however, larger studies are clearly needed to verify these findings. Other studies have shown that doxepin significantly reduces postcessation tobacco withdrawal symptoms and cigarette craving [226, 227].

15.3.4.3 Cannabinoid Antagonists. The cannabinoid-1 (CB1) receptor plays a role in the regulation of appetitive behavior. For example, exogenously administered cannabinoid receptor agonists stimulate food consumption in animals and humans [228]. The endocannabinoid system appears to mediate the effects of nicotine in rodents. For example, rimonabant, a CB1 receptor antagonist, appears to decrease the motivational effects of nicotine in the rat [229]. Administration of rimonabant (0.3 and 1 mg/kg) decreases nicotine self-administration (0.03 mg/kg/injection). Rimonabant (0.3–3 mg/kg) neither substitutes for nor antagonizes the nicotine cue in a nicotine discrimination procedure. In addition, using brain microdialysis, rimonabant (1–3 mg/kg) blocks nicotine-induced DA release in the shell of the nucleus accumbens and the bed nucleus of the stria terminalis. These results suggest that activation of the endogenous cannabinoid system may participate in the motivational and DA-releasing effects of nicotine.

Rimonabant is one such cannabinoid antagonist that has been recently tested in clinical trials which were reported in the news media. The study reveals that the medication was efficacious for smoking cessation. Also, smokers who quit in the rimonabant group gain less weight than those that quit in the placebo group. Many smokers report weight gain to be one of the factors associated with relapse [230]; thus a medication that reduces the weight gain associated with cessation may decrease the likelihood of relapse during a quit attempt.

15.3.4.4 Opioid Antagonists. As reviewed by Pomerleau [231], opiate agonists such as heroin or methadone have been found to increase cigarette smoking reliably in humans, and morphine has been shown to increase the potency and efficacy of nicotine in rats. There is also an extensive literature documenting the nicotine-

stimulated release of endogenous opioids in various brain regions involved in the mediation of opiate reinforcement. In addition, the opioid system may be involved in the reinforcing properties of several drugs of abuse and may be involved in nicotine's reinforcing properties. This may imply that opioid antagonists may attenuate the reinforcing value of cigarette smoking. Naltrexone is an opioid antagonist that has been shown to be effective for the treatment of alcohol dependence and has recently been approved for this indication by the FDA [232]. Two studies have examined the effects of naltrexone during smoking abstinence [92, 233]. These studies generally demonstrate little effect of naltrexone on tobacco withdrawal, smoking behavior, or satisfaction from smoking. Currently available data provide little support for the use of naltrexone for the treatment of tobacco dependence or withdrawal.

15.3.5 Nicotine Pharmacology Implications for Public Health Policy

The importance of the emerging understanding of nicotine as an addictive or dependence-producing drug over the twentieth century has had profound implications for public health policy, is the foundation for efforts by the FDA to regulate tobacco products, and was the cornerstone of the WHO Framework Convention on Tobacco Control (FCTC) [5, 234, 235]. Succinctly stated, regulatory efforts in the United States and many other countries are endeavoring to address tobacco through a combination of demand reduction and supply control efforts that recognize that tobacco use is driven and sustained critically by the pharmacological effects of nicotine.

As is evident from the preceding section of this review, many effective pharmacological treatment strategies have emerged and many more are in various stages of the drug development pipeline. The U.S. Public Health Service advocates that all cigarette smokers be offered treatment, so favorable is the benefit-to-risk ratio [187]. Globally, the WHO [189] and World Bank [236] both recommend that expanded treatment access and utilization are vital to the health, well-being, and economic development of all nations.

In the decades to come, treatment access will be vital to global health. In the very long range, however, reducing demand by more effective tobacco use prevention efforts and the prevention of escalation to dependence will be equally vital. Here, as well, nicotine pharmacology plays a potentially vital role in the needed partnership between prevention and treatment researchers. The rapid development of nicotine tolerance, dependence, and altered brain structure that contribute to persistent tobacco use are factors to be considered in public health efforts to reduce exposure to tobacco, erect barriers to reduce the conversion from any use to dependence, and develop more effective early interventions to steer the trajectory of tobacco use from addiction to abstinence. Animal and human research with nicotine and other addictive drugs has shown the importance of drug-associated stimuli in persistent use and relapse, the importance of efforts to reduce opportunities for use, and reducing overall use through increased cost. These findings are being adapted to public health policy through actions including the following: laws reducing access of youth to tobacco, increasing taxes and hence cost of tobacco products, and efforts to reduce the ubiquity of tobacco dependence-associated stimuli [5, 236, 237]. Additional approaches under consideration are parallel to those taken with medications

with abuse potential, namely, to reduce the abuse liability to the greatest degree possible without rendering the product so unacceptable that the effort would simply drive people to other forms of tobacco. Although we do not intend to over represent the importance of behavioral and pharmacological sciences in public health efforts to control one of the world's greatest public health disasters, it is clear that scientific investigation in this area has been vital to global health. As evidenced by this review, research advances have been rapid. The rapidity of these advances implies that future decades will witness even more powerful tools to bring tobacco addiction and associated disease under control. Taken together, in the decades to come, former Surgeon General C. E. Koop's vision that the end of the twenty-first century will be a time when tobacco-associated death will be as rare as it was at the end of the nineteenth century [238] eventually may be realized.

ACKNOWLEDGMENTS

The authors acknowledge the work of A. Markou, G. F. Koob, and J. E. Henningfield (2003) as a model for Section 15.2.

DISCLOSURES

A. R. Buchhalter, R. V. Fant, and J. E. Henningfield serve as consultants to GlaxoSmithKline Consumer Healthcare regarding matters relating to smoking cessation. J. E. Henningfield also has a financial interest in a new nicotine replacement product.

16.1 INTRODUCTION

Psychostimulants are a broadly defined class of drugs that stimulate the central and sympathetic peripheral nervous systems as their primary pharmacological effect. In humans, psychostimulants reliably elevate mood and promote wakefulness. In animals, psychostimulants increase locomotor activity and reliably maintain self-administration behavior indicative of robust reinforcing effects. The abuse liability of psychostimulants is well established and represents a significant public health concern. Cocaine is widely recognized as one of the most addictive and dangerous illicit drugs in use today. The most recent proceedings of the National Institute on Drug Abuse (NIDA) Community Epidemiology Work Group (CEWG), published in 2003, reported that cocaine and crack abuse was endemic in almost all 21 major U.S. metropolitan areas surveyed. Rates of emergency department visits per 100,000 population were higher for cocaine than for any other illicit drug in 17 areas, and trends in treatment admissions from 2000 to 2002 showed little change in most areas

surveyed. Drug abuse–related emergency department visits involving amphetamine or methamphetamine increased 54% in the United States between 1995 and 2002. Currently, no effective pharmacotherapy for psychostimulant abuse has demonstrated efficacy for long-term use. Clearly, a better understanding of the neuropharmacological effects of cocaine and related psychostimulants will support efforts to develop and improve useful pharmacotherapies for psychostimulant abuse.

It is important to emphasize that a number of synthetic stimulants, including amphetamines, are useful medications in the treatment of attention-deficit hyperactivity disorder (ADHD), narcolepsy, excessive daytime sleepiness, and obesity. Cocaine is still used clinically as a local anesthetic, primarily for eye, ear, nose, or throat procedures. Some examples of stimulant medications legally available in the United States and their medical indications are provided in Table 16.1. Most of these drugs are analogs of the basic phenethylamine chemical structure closely related to the catecholamine neurotransmitters norepinephrine and dopamine (Fig. 16.1). The present chapter will focus on the neuropharmacology of cocaine, amphetamine, and methamphetamine due to their high abuse potential as reflected in their categorization as Schedule II drugs (Federal Controlled Substances Act). Other stimulants have potential for abuse and dependence due to their similar profile of pharmacological effects. For example, it is well established that methylphenidate is diverted from legitimate sources, such as Ritalin, and is misused or abused by a segment of the U.S. population [1]. However, the neuropharmacology of methylphenidate will be reviewed in a separate chapter on ADHD and stimulants. Also, there are a number of illicit amphetamine derivatives, including 3,4-methylenedioxymethamphetamine (MDMA, “Ecstasy”), that have prominent stimulant and hallucinogenic properties. The latter drugs will be reviewed in Chapter 17 focused on MDMA and other “club drugs”. Recently, neurotoxicity associated with the use of amphetamine derivatives has been an area of intense investigation.

TABLE 16.1 Examples of Psychostimulants Used as Therapeutics in the United States

Drug	Trade Names	Medical Indications
Amphetamine	Adderall [®] Dexedrine [®] Dextrostat [®]	ADHD, narcolepsy, weight control
Diethylpropion	Tenuate [®]	Weight control
Methamphetamine	Adipex [®] Desoxyn [®] Methedrine [®]	ADHD, weight control
Methylphenidate	Ritalin [®]	ADHD, narcolepsy
Phentermine	Adipex-P [®] Fastin [®] Ionamin [®]	Weight control

Figure 16.1 Chemical structures of endogenous and exogenous ligands for dopamine receptor. Dopamine and norepinephrine are both endogenous catecholamine neurotransmitters, sharing several chemical features, notably a catechol ring and an amine group. Exogenous ligands for the dopamine transporter, including amphetamine, methamphetamine, diethylpropion, phentermine, and methylphenidate, also share these chemical characteristics and act as psychomotor stimulants.

16.2 NEUROPHARMACOLOGY RELATED TO PSYCHOSTIMULANT ABUSE

Extensive literature documents the critical importance of monoamines (dopamine, serotonin, and norepinephrine) in the behavioral pharmacology and addictive properties of psychostimulants. In particular, dopamine plays a primary role in the reinforcing effects of psychostimulants in animals and humans. However, there is a growing body of evidence that highlights complex interactions among additional neurotransmitter, neuroendocrine, and neuropeptide systems. Cortical glutamatergic systems provide important regulation of dopamine function. Similarly, γ -aminobutyric acid (GABA) systems provide inhibitory neuromodulation of monoaminergic and glutamatergic function. Psychostimulants also activate the hypothalamic–pituitary axis and thereby engage neuroendocrine systems linked to stress reactivity. Alternatively, environmental stressors can alter the neurochemical and behavioral effects of psychostimulants. Finally, endogenous neuropeptide systems, including opioids and neurotensin, appear to play an important role in the neuropharmacology and addictive properties of psychostimulants. Drug abuse and addiction comprise a

highly complex behavioral disorder. It is not surprising that the neurobiological substrates underlying psychostimulant abuse and dependence involve a complex interplay among multiple neurochemical systems.

16.2.1 Monoamines

The primary mechanism for inactivation of monoamine signaling is transporter-mediated uptake of released monoamine neurotransmitters. Psychostimulants enhance monoamine signaling by interfering with transporter function (Fig. 16.2). However, psychostimulants differ in their relative affinity for dopamine, serotonin, and norepinephrine transporters. For example, cocaine has approximately equal

Figure 16.2 Representative dopaminergic nerve terminal and synapse. Dopamine is packaged into vesicles in the presynaptic neuron via VMAT2. Once dopamine is released into the synapse, this neurotransmitter can bind to postsynaptic dopamine receptors, including the D₁, D₂, and D₃ dopamine receptors. Dopamine D₂ receptors are also localized at the presynaptic terminal, acting as a feedback mechanism to regulate dopamine release. The DAT is also located at the presynaptic terminal and functions to remove dopamine from the synapse. Psychostimulants act at the DAT to alter normal dopamine receptor functions. Cocaine blocks the DAT, inhibiting uptake of dopamine into the presynaptic nerve terminal. Amphetamine also blocks the DAT and inhibits dopamine uptake, but also acts to release dopamine from intracellular vesicles. Abbreviations: A, amphetamine; C, cocaine; DAT, dopamine transporter; VMAT2, vesicular monoamine transporter 2.

TABLE 16.2 Drug Affinities at Monoamine Transporters

Drug	Dopamine	Serotonin	Norepinephrine
Cocaine	478 ^a	304 ^a	777 ^b
(+) Amphetamine	34 ^b	3830 ^b	39 ^b

affinity for these three transporters (Table 16.2). In contrast, amphetamine, methamphetamine, and methylphenidate all have relatively lower affinity for serotonin transporters compared to their affinity for dopamine and norepinephrine transporters. In addition, psychostimulants differ in their actions as reuptake inhibitors versus substrate-type releasers [2, 3]. Reuptake inhibitors bind to transporter proteins and interfere with transporter function but are not transported into the nerve terminal. Cocaine is an example of a reuptake inhibitor. In contrast, substrate-type releasers bind to transporter proteins and are subsequently transported into the cytoplasm of the nerve terminal. Releasers elevate extracellular monoamine levels by reversing the process of transporter-mediated exchange, thereby enhancing monoamine efflux. They also increase cytoplasmic levels of monoamines by interfering with vesicular storage [4, 5]. Amphetamine and methamphetamine are examples of substrate-type releasers. Typically, releasers are more effective than reuptake inhibitors in increasing extracellular monoamines because the former increase the pool of neurotransmitters available for release by transporter-mediated exchange. Moreover, the effectiveness of releasers in increasing extracellular monoamines is not dependent upon the basal rate of neurotransmitter release. In contrast, the effectiveness of reuptake inhibitors is impulse dependent and, therefore, limited by the tone of presynaptic activity.

In vivo studies have demonstrated that psychostimulants can interact with multiple monoamine transporters. However, the behavioral effects of psychostimulants associated with their addictive properties have been linked most closely to enhanced dopaminergic activity. The mesocorticolimbic dopamine system comprises dopamine neurons originating in the ventral tegmental area (VTA) of the midbrain that project to several limbic and cortical structures, including the nucleus accumbens, amygdala, and prefrontal cortex [6, 7] (Fig. 16.3). Drug-induced increases in extracellular dopamine in the mesocorticolimbic dopamine system are critical in mediating the behavioral effects of psychostimulants. Two families of dopamine receptors termed D₁-like (D₁ and D₅ receptors) and D₂-like (D₂, D₃, and D₄ receptors) have been described [8, 9], and both have been implicated in the abuse-related effects of cocaine [10–12]. Evidence to support this conclusion is derived from a variety of behavioral studies characterizing the acute effects of direct-acting dopamine agonists, dopamine uptake inhibitors, and dopamine antagonists administered alone or in combination with cocaine and related psychostimulants. Operant-conditioning procedures have been implemented to characterize drug effects on behavior, including schedule-controlled behavior (model of stimulant effects),

Figure 16.3 (a) Rat brain showing major components of mesolimbic system. Dopamine neurons project from the VTA and terminate in the NAc. Inhibitory GABA neurons project from the NAc and terminate in the VTA. Excitatory glutamatergic neurons project from the PFC to the NAc and to the VTA. (b) Human brain showing major dopaminergic projections. Abbreviations: BG, basal ganglia; LC, locus coeruleus; Hipp, hippocampus; Hypo, hypothalamus; NAc, nucleus accumbens; PFC, prefrontal cortex; SN, substantia nigra; VTA, ventral tegmental area.

drug self-administration (model of reinforcing effects), reinstatement (model of relapse), and drug discrimination (model of subjective effects) [13].

In a series of comprehensive studies, a significant correlation was obtained between dopamine transporter occupancy *in vitro* and the locomotor stimulant effects of cocaine analogs [14, 15]. In addition, the inhibition constants of 19 different dopamine transporter inhibitors were highly and positively correlated with their discriminative stimulus effects in rodents trained to discriminate cocaine from saline [16]. Similarly, a high correlation was found between the ability of cocaine analogs to displace [^3H]cocaine in the caudate and the ability of those compounds to produce cocaine like behavioral effects in squirrel monkeys [17–19]. Cocaine and selective dopamine uptake inhibitors exert similar effects on schedule-controlled behavior and are reliably self-administered in monkeys [17, 20–23]. Moreover, some direct-acting dopamine agonists maintain self-administration in rodents [24] and monkeys [25, 26]. Lastly, dopamine antagonists can attenuate specific behavioral effects of cocaine, including its reinforcing effects [27], its discriminative stimulus effects [28–30], and its stimulant effects on schedule-controlled behavior [20, 31–33]. The results obtained in behavioral studies provide compelling evidence that dopamine plays a major role in the neuropharmacology of cocaine.

The relevance of the dopamine transporter in the reinforcing effects of cocaine is supported further by human and nonhuman primate neuroimaging studies. In human cocaine users, a significant correlation was observed between dopamine transporter occupancy and the subjective high reported following administration of cocaine [34] or the behavioral stimulant methylphenidate [35]. Doses of cocaine within the range used by humans resulted in dopamine transporter occupancy between 67 and 69% in baboons [36]. Moreover, doses of cocaine that maintained peak response rates in drug self-administration studies resulted in dopamine transporter occupancy between 65 and 76% in rhesus monkeys [37, 38]. In addition, dopamine transporter occupancy has been determined for dopamine transporter inhibitors shown to be effective in reducing cocaine self-administration. Doses of GBR 12909 that decreased cocaine self-administration in rhesus monkeys resulted in dopamine transporter occupancy greater than 50% in baboons [39] and rhesus monkeys [38]. Similarly, doses of phenyltropane derivatives of cocaine with selectivity for the dopamine transporter decreased cocaine self-administration in rhesus monkeys at dopamine transporter occupancies between 72 and 84% [37, 38]. Collectively, these results indicate that dopamine transporter occupancy is an important determinant of the reinforcing effects of cocaine and of the effectiveness of dopamine transporter inhibitors to reduce cocaine self-administration.

The dopaminergic system is clearly an important site of action for psychostimulants, but preclinical studies have indicated that the serotonergic system can effectively modulate the behavioral effects of cocaine and amphetamine. Although compounds that selectively increase serotonin (5-HT) neurotransmission lack behavioral stimulant effects and do not reliably maintain self-administration behavior [40, 41], a negative relationship was observed between the potencies of several cocaine- and amphetamine-like drugs in self-administration studies and their binding affinities for 5-HT uptake sites [42, 43]. Coadministration of agents that induce robust increases in both dopamine and 5-HT produces minimal behavioral stimulant effects [44] and does not maintain self-administration behavior [45] in rodents. Similarly, monoamine-releasing agents have decreased reinforcing efficacy in rhesus

monkeys when 5-HT-releasing potency is increased relative to dopamine [46]. The behavioral and neurochemical profile of dopamine transporter inhibitors is also influenced by their actions at multiple monoamine transporters in squirrel monkeys [47]. Consistent with these results, administration of the 5-HT uptake inhibitor fluoxetine decreased self-administration of cocaine [48] and amphetamine [49] in rodents and self-administration of cocaine in rhesus monkeys [50]. In nonhuman primate studies, the 5-HT uptake inhibitors citalopram, fluoxetine, and alaproclate attenuated the behavioral stimulant effects of cocaine on schedule-controlled behavior [41, 51]. The 5-HT direct agonist quipazine also attenuated the behavioral stimulant effects of cocaine, whereas the 5-HT antagonists ritanserin and ketanserin enhanced the behavioral stimulant effects of cocaine [41]. Lastly, the 5-HT uptake inhibitor alaproclate attenuated cocaine self-administration and cocaine-induced increases in extracellular dopamine in squirrel monkeys [52] and cocaine-induced activation of prefrontal activity in rhesus monkeys [53]. Collectively, there is a growing body of evidence to suggest that increasing brain 5-HT activity can attenuate the behavioral stimulant and reinforcing effects of psychostimulants.

Brain 5-HT systems are ideally situated to modulate the activity of dopamine neurons and the behavioral effects of dopamine uptake inhibitors such as cocaine. Serotonin neurons from the dorsal and median raphe nuclei innervate the dopaminergic cell bodies and terminal regions of the nigrostriatal and mesolimbic dopamine systems, and the convergence of 5-HT terminals and dopamine neurons has been visualized in the VTA and nucleus accumbens at the light and electron microscopic levels [54, 55]. Serotonin can act on cell bodies to decrease the firing rate of dopamine neurons or at terminals to decrease dopamine release. In either case, the ability of 5-HT to attenuate the behavioral effects of cocaine may result from an attenuation of cocaine-induced elevation of extracellular dopamine. Alternatively, 5-HT may act postsynaptically to dopamine neurons, attenuating the effects of cocaine-induced increases of extracellular dopamine on a downstream component of the pathway.

There is a growing consensus that stimulation of 5-HT_{2C} receptors inhibits the function of the mesolimbic dopamine system [56]. Firing rates of dopamine neurons in the VTA are decreased by 5-HT uptake inhibitors [57] and selective 5-HT_{2C} agonists [58], resulting in a decrease in nucleus accumbens dopamine levels [59]. Conversely, selective 5-HT_{2C} antagonists increase the activity of these neurons [60], leading to increased dopamine release in the nucleus accumbens [61]. Since 5-HT_{2C} receptors appear to be located exclusively on GABA neurons [62], the effects of 5-HT_{2C} receptor stimulation are likely to be indirectly mediated by an enhancement of GABA-mediated inhibition of VTA dopamine neurons. Localization of 5-HT_{2C} receptors on GABAergic terminals may also explain the conflicting results which have been obtained in previous electrophysiological, neurochemical, and behavioral studies. Some studies investigating interactions between 5-HT and dopamine have concluded that 5-HT can exert an excitatory influence on dopamine activity [63] and release [64, 65]. Stimulation of 5-HT_{1B} receptors can enhance cocaine reinforcement [66], likely by decreasing GABA-mediated inhibition in the VTA [63]. The 5-HT₃ receptors also appear to play a facilitatory role in the behavioral effects of dopamine agonists [67, 68]. These seemingly disparate results likely reflect the complexity of interactions between 5-HT and dopamine systems and the 5-HT receptor subtypes influenced by drug administration.

The norepinephrine system has considerable anatomical and functional connectivity to the mesolimbic dopamine system. There is significant noradrenergic innervation of the shell subregion of the nucleus accumbens [69, 70]. The locus ceruleus, the primary norepinephrine nucleus in the brain, projects directly to the VTA and influences neuronal firing of dopamine neurons [71]. Stimulation of the locus ceruleus can increase the activity of VTA dopamine neurons, and this effect is blocked by an α_1 adrenoreceptor antagonist [72]. In addition, lesions of the locus ceruleus can decrease basal release of dopamine in the nucleus accumbens [73]. It appears that interactions between norepinephrine and dopamine may play an important role in the behavioral pharmacology of psychostimulants. For example, amphetamine-induced release of dopamine in the nucleus accumbens and conditioned place preference to amphetamine are attenuated following depletion of norepinephrine in the prefrontal cortex of rodents [74]. Lesion of the locus ceruleus or inactivation of α_1 adrenoreceptors can also attenuate amphetamine- and cocaine-induced locomotion and sensitization in rodents [75–77]. Similarly, α_2 adrenoreceptor agonists which decrease norepinephrine release via autoreceptor activation block stress-induced reinstatement of extinguished cocaine self-administration behavior in rodents [78]. Studies in nonhuman primates also support a role for norepinephrine uptake and α_1 adrenoreceptor mechanisms in the discriminative stimulus effects of cocaine [79]. There is also a significant positive correlation between potency of norepinephrine release *in vitro* and the oral stimulant dose that produces stimulant-like subjective effects in humans [80]. However, it should be noted that there is little evidence that norepinephrine plays a primary role in the reinforcing properties of psychomotor stimulants in rodents [81] or nonhuman primates [41, 82–84].

16.2.2 Glutamate

The interaction between glutamatergic and dopaminergic systems has been an area of increasing interest in drug abuse and mental health research. Anatomical substrates for glutamate–dopamine interactions have been well characterized in rodents [85]. Dopaminergic afferents from the VTA to the dorsal striatum, nucleus accumbens, and prefrontal cortex are positioned to modulate glutamate function. Conversely, the VTA, dorsal striatum, and nucleus accumbens receive significant glutamatergic innervation from a variety of brain regions, including the prefrontal cortex, hippocampus, basolateral amygdala, and thalamus. Electrophysiological studies have documented complex functional interactions between glutamatergic and dopaminergic systems that play a primary role in frontal–subcortical circuits involved in motor and cognitive function [86]. Behavioral studies have documented that interactions between dopaminergic and glutamatergic inputs in the dorsal striatum and nucleus accumbens contribute to the expression of a variety of psychomotor behaviors in rodents relevant to drug addiction [87]. Importantly, a substantial literature derived from rodent studies has documented that glutamate receptor function plays a major role in the behavioral pharmacology of cocaine and other psychomotor stimulants. In particular, glutamatergic systems have been implicated in the development of locomotor sensitization, conditioned place preference, drug self-administration, and reinstatement of extinguished drug self-administration behavior [88–92].

The excitatory effects of glutamate can be mediated by ionotropic and metabotropic receptors, and localization of both receptor families in the VTA has been documented [93]. Recent evidence indicates that metabotropic glutamate receptors (mGluRs) play an important role in the behavioral effects of cocaine associated with its abuse liability. mGluRs can be divided into three groups based on sequence homology, receptor pharmacology, and signal transduction mechanisms [94]. Group I consists of mGluR1 and mGluR5 and is linked to phospholipase C and phosphoinositide hydrolysis. Group II consists of mGluR2 and mGluR3, while group III consists of mGluR4, 6, 7, and 8. Both groups II and III are negatively coupled to adenylyl cyclase. Group II mGluRs function as autoreceptors to regulate presynaptic glutamate release [94] and as heteroreceptors to regulate release of other neurotransmitters, including dopamine [95]. Administration of an mGluR2/3 agonist decreased dopamine and glutamate release in the nucleus accumbens, striatum, and prefrontal cortex [95–98], suggesting that glutamatergic tone on mGluR2/3 suppresses extracellular levels of dopamine and glutamate. The primary origin of extrasynaptic glutamate appears to be nonvesicular glutamate regulated by cystine/glutamate transporters [98, 99]. Withdrawal from repeated exposure to cocaine in rodents led to reduced levels of extracellular glutamate in the nucleus accumbens due to reductions in cystine/glutamate exchange [100, 101]. Restoration of cystine/glutamate exchange by systemically administered *N*-acetylcysteine (NAC) normalized glutamate levels in cocaine-treated rats. Importantly, cocaine-induced reinstatement of extinguished self-administration behavior was prevented by NAC-induced restoration of extracellular glutamate. Overall, a growing body of evidence derived from rodent studies indicates that glutamate plays a fundamental role in the maintenance and reinstatement of stimulant self-administration behavior [102–104]. Lastly the mGluR5 subtype has also been implicated in cocaine self-administration. mGluR5-deficient mice did not acquire intravenous (i.v.) self-administration of cocaine, and pretreatment with the mGluR5 antagonist MPEP decreased cocaine self-administration without affecting food-maintained behavior under similar schedules of reinforcement in rats [105]. Similarly, MPEP dose dependently attenuated the development of conditioned place preference in mice [106] and suppressed cocaine self-administration behavior in squirrel monkeys [107].

16.2.3 γ -Aminobutyric Acid

The inhibitory amino acid GABA is widely distributed in the central nervous system (CNS) and can modulate basal dopamine and glutamate release [108]. The VTA contains GABAergic inhibitory interneurons that function to control the firing rate of VTA dopamine neurons [109–111]. Moreover, the majority of projection neurons in the nucleus accumbens are GABAergic neurons, some of which project to the VTA and regulate the activity of dopamine neurons [112]. Several studies have indicated that GABAergic compounds can reliably modulate the neurochemical and behavioral effects of cocaine [113, 114]. Allosteric GABA_A agonists, such as benzodiazepines and barbiturates, can inhibit dopamine and glutamate activity but have prominent sedative and hypnotic effects. However, there is considerable interest in GABA_B agents, such as baclofen, due to their attenuation of glutamate and dopamine release [108, 115, 116] and their suppression of cocaine self-administration behavior across a wide range of schedules of reinforcement and access conditions

[114, 117–119]. In addition, pharmacological inhibition of GABA transaminase, the major enzyme involved in the metabolism of GABA, can lead to a rapid increase in extracellular GABA and a corresponding attenuation of cocaine self-administration behavior at doses that do not influence locomotor activity [120, 121]. Inhibition of GABA transaminase activity with γ -vinyl GABA can also block cocaine-induced lowering of brain stimulation reward thresholds [122]. Although psychostimulants do not have direct pharmacological effects on GABAergic systems, there is convincing evidence that GABA can modulate the neurochemical and behavioral effects of psychostimulants.

16.2.4 Hypothalamic–Pituitary–Adrenal Axis

The hypothalamic–pituitary–adrenal (HPA) axis is a neuroendocrine system that responds to stress, resulting in the release of glucocorticoids from the adrenal cortex. The mature HPA axis exhibits a circadian rhythmicity with a peak around the time of waking and a trough during the quiescent time of the activity cycle. Superimposed upon this diurnal pattern is activation of stressor-specific pathways that converge in the hypothalamus, where information is integrated in the paraventricular nucleus by parvocellular neurons expressing corticotropin-releasing factor (CRF). CRF is released from nerve endings in the median eminence in response to metabolic, psychological, or physical threats and stimulates the release of adrenocorticotrophic hormone (ACTH) from the anterior pituitary. ACTH, in turn, stimulates the release of glucocorticoids (cortisol in primates, corticosterone in rats) from the adrenal cortex. These steroid hormones mobilize energy substrates during stress and regulate activity of the HPA axis via negative feedback at different levels via two types of corticosteroid receptors: (a) mineralocorticoid receptors involved in the modulation of the circadian HPA rhythm and (b) glucocorticoid receptors primarily responsible for reactive negative feedback during the circadian peak and following an acute stressor. In addition to its endocrine effects, CRF has a broad extrahypothalamic distribution in the CNS [123], and its synthesis and function are affected by stress [124].

Glucocortical hormones have a facilitory role in behavioral responses to psychostimulants, including locomotor activity, self-administration, and reinstatement of extinguished self-administration behavior. These interactions appear to involve glucocorticoid effects on the mesolimbic dopamine system [125, 126]. Suppression of glucocorticoids by adrenalectomy reduces the psychomotor stimulant effects of cocaine [127] and amphetamine [128, 129], and this effect is reversed by corticosterone administration [128]. Although psychostimulants increase corticosterone secretion [130], there is no correlation between drug-induced locomotion and drug-induced corticosterone increase [131, 132]. Similarly, reductions in circulating corticosterone attenuate the reinforcing effects of psychostimulants [133, 134]. However, blocking psychostimulant-induced elevations in glucocorticoid secretion does not affect cocaine self-administration [135–138]. Finally, corticosterone appears to play an important role in cue- and stress-induced reinstatement of extinguished self-administration behavior but not drug-induced reinstatement. Ketoconazole, which decreases glucocorticoid levels, prevents reinstatement induced by drug-paired environmental stimuli [138, 139]. Similarly, basal levels of corticosterone are necessary for stress-induced reinstatement even though stress-induced increases in corticosterone are not required [140, 141]. Moreover, stress-induced reinstatement

can be blocked by corticotropin-releasing hormone (CRH) antagonists, suggesting that extra-hypothalamic CRH plays a role in stress-induced reinstatement [140, 142]. In contrast, cocaine-induced reinstatement is minimally influenced by adrenalectomy [140] and is not affected by ketoconazole administration [143].

16.2.5 Neuropeptides

All three opioid receptor subtypes (μ , κ , and δ) have been localized within dopamine systems in rodents [144–147]. Accordingly, it is not surprising to find interactions between the effects of drugs that primarily target these systems. As discussed earlier in this chapter, psychomotor stimulants interact directly with the dopamine system, either by blocking the dopamine transporter (as in the case of cocaine) or by stimulating dopamine release (as in the case of amphetamine). In contrast, opioid interactions with the dopamine systems are indirect. The μ - and δ -opioid receptors are located on GABAergic cells, which normally inhibit dopamine neurons. Activation of these receptors suppresses the activity of these inhibitory GABAergic interneurons, releasing the inhibition of dopamine cells, thereby increasing dopamine release from terminals [148–151]. In contrast, κ -opioid receptors are found on dopamine nerve terminals [152, 153], directly inhibiting dopamine release [145, 148, 154, 155].

Cocaine and heroin are often abused together in a “speedball” combination, resulting in euphoric effects that are greater than those of either drug alone [156, 157]. Preclinical research indicates that the combined administration of psychomotor stimulants and opiates enhances the effects of the individual drugs in several different behavioral assays. In rodent locomotor assays, μ -opioid receptor agonists potentiated the stimulant effects of cocaine and amphetamine [158–160]. The μ -opioid receptor agonists also potentiated the discriminative stimulus effects of cocaine in squirrel monkeys [161, 162]. However, drug self-administration studies in both rats [163] and rhesus monkeys [164] indicated that the combination of cocaine and heroin was not more reinforcing than cocaine alone. In contrast to the μ -opioid receptor agonists, the κ -opioid receptor agonist U-69593 attenuated cocaine- [165] and amphetamine- [166, 167] induced activity in rodents. Similarly, the κ -opioid receptor agonist U50488 attenuated the discriminative stimulus effects of low doses of cocaine in squirrel monkeys [168]. The results of stimulation of δ -opioid receptors on the behavioral effects of cocaine have been inconsistent [169]. The δ -opioid receptor agonist DPDPE potentiated cocaine-induced increases in locomotor activity in rodents [170]. However, the δ -opioid receptor antagonist naltrindole did not alter cocaine self-administration or cocaine-induced conditioned place preference in rodents [171]. The effects of the δ -opioid receptor agonist BW 373U86 did not alter the discriminative stimulus effects of cocaine in squirrel monkeys in one study [168], but in another study, the high-efficacy δ -opioid receptor agonist SNC80 potentiated the discriminative stimulus effects of cocaine [162].

Opiates not only influence psychomotor stimulant-induced changes in behavior but also alter psychomotor stimulant-induced changes in extracellular dopamine in the striatum and nucleus accumbens. When given in combination with cocaine, μ -opioid receptor agonists enhanced cocaine-induced increases in extracellular dopamine in rats [172, 173]. In contrast, κ -opioid receptor agonists attenuated cocaine- and amphetamine-induced increases in extracellular dopamine [167, 174].

Neurotensin is colocalized in tyrosine hydroxylase-containing dopamine neurons in the rat VTA and prefrontal cortex [175, 176]. Direct injections of neurotensin into selected brain regions results in changes in neurochemistry and behavior that are similar to those observed after administration of psychomotor stimulants. *In vitro* and *in vivo* studies show that neurotensin increases the firing of dopamine neurons in several brain regions, including the VTA [176, 177]. Intracerebroventricular administration of neurotensin increased levels of dopamine and its metabolites in several brain areas, including the striatum and nucleus accumbens [178, 179]. Infusion of neurotensin into the striatum or the VTA, but not into the nucleus accumbens, increased extracellular dopamine levels in rats [180, 181]. Repeated infusion of neurotensin into the VTA resulted in an enhanced dopamine response compared to an acute injection [180]. Locomotor activity was increased following infusion of neurotensin into the VTA of rats [180, 182] and sensitization to this behavioral effect was apparent after repeated neurotensin treatment [183]. Although rats self-administered neurotensin directly to the VTA [184], the neurotensin receptor agonist NT69L was not self-administered by rhesus monkeys [185].

Changes in dopamine neurotransmission following neurotensin administration are also reflected in alterations of psychostimulant-induced changes in neurochemistry and behavior. Direct neurotensin infusion to the striatum attenuated increases in dopamine induced by low, but not high, cocaine doses in rats [181]. In contrast, neurotensin did not block amphetamine-induced increases in dopamine in the nucleus accumbens [186]. Intravenous or intra-accumbal injections of neurotensin attenuated cocaine- and amphetamine-induced increases in locomotor activity in the rat [187–189]. Similarly, systemic administration of the neurotensin receptor agonist NT69L blocked the acute locomotor effects of cocaine and amphetamine in rats [190, 191]. Repeated, but not acute, administration of the selective neurotensin antagonist SR48692 decreased cocaine-induced increases in locomotor activity in rats [192]. Although neurotensin can alter the neurochemical and behavioral stimulant effects of psychostimulants, it may not play an important role in the reinforcing effects of these drugs. Direct application of neurotensin into the nucleus accumbens did not alter cocaine self-administration in rats [189], and the neurotensin receptor agonist NT69L did not alter the reinforcing effects of cocaine in rhesus monkeys [185].

16.3 NEUROBIOLOGY OF CHRONIC PSYCHOSTIMULANT EXPOSURE

Repeated exposure to psychostimulants can lead to robust and enduring changes in neurobiological substrates and corresponding changes in sensitivity to acute drug effects on neurochemistry and behavior. Diminished sensitivity to the effects of a drug during repeated exposure is indicative of tolerance, whereas enhanced sensitivity is indicative of sensitization. Both tolerance and sensitization have been reported to develop during repeated administration of stimulants in animal studies [193]. However, the outcome depends upon a variety of procedural variables, including the drug effect under investigation, the dosing regimen, the environmental context associated with drug administration, and the animal species. The vast majority of studies have focused on sensitization to locomotor stimulant effects in rodent models. Stimulants including cocaine and amphetamines can produce robust sensitization in

rodents, usually identified as a progressive increase in locomotor activity or stereotyped behavior with repeated drug dosing [194]. In fact, sensitization has been proposed as a general model of neural plasticity whereby drug-induced changes in behavior can be linked to concomitant changes in molecular mechanisms. It is important to emphasize that some neurobiological changes are not evident when drug administration is terminated but actually emerge during the period of drug withdrawal.

16.3.1 Neurotransmitter and Neuroendocrine Systems

There is substantial evidence that the mesocorticolimbic dopamine system and its excitatory glutamatergic inputs are critical for the development of sensitization to the behavioral effects of psychostimulants [91, 195]. Studies involving microinjection of drugs into discrete brain regions have indicated that the VTA, a region rich in dopamine cell bodies, plays a critical role in the development of sensitization. In contrast, the nucleus accumbens, a major dopamine projection area from the VTA, appears to be more closely linked to the expression of sensitization. For example, microinjections of dopamine D₁ receptor antagonists [196, 197] or glutamate *N*-methyl-D-aspartate (NMDA) receptor antagonist [198] into the VTA can disrupt the development of sensitization. However, glutamate NMDA antagonists do not block the expression of sensitization [199]. Similarly, dopamine antagonists can block the development of sensitization to psychostimulants without blocking its expression [200]. Glutamatergic afferents from the prefrontal cortex to the VTA and the nucleus accumbens have been implicated in both the development and expression of sensitization to cocaine and amphetamine [201]. Sensitized animals also reliably show an augmented response to drug-induced increases in extracellular glutamate and dopamine in the nucleus accumbens [88, 202]. Collectively, there is convincing evidence to suggest that glutamatergic afferents from the prefrontal cortex produce adaptations in the VTA that mediate the development of sensitization to psychostimulants and that secondary adaptations within the nucleus accumbens are necessary for the expression of sensitization.

Behavioral sensitization to stimulants, including cocaine, amphetamine, and methylphenidate, also involves neuroadaptation of stress-responsive systems, in particular the HPA axis and CRF pathways. In fact, there is a dynamic crosstalk between these systems. Stimulants affect HPA axis function, but there is also evidence that exposure to stress or stress hormones increases sensitivity to stimulants [136, 203]. The latter effect has been linked to glucocorticoid effects on dopaminergic neurotransmission [203, 204]. Repeated exposure to stimulants in adult rodents produces long-term increases in HPA axis activity, resulting in enhanced ACTH and corticosterone secretion [204–206]. Studies of chronic administration of methylphenidate in periadolescent rats have found similar long-term effects in adulthood, such as increased HPA axis and behavioral (anxiety-like) stress reactivity [207]. Another long-term effect of stimulants on the central components of the HPA axis of the rat includes the downregulation of hippocampal and cerebral cortex glucocorticoids that could affect glucocorticoid-induced negative feedback on HPA axis activity [208, 209]. Stimulants also induce alterations of extrahypothalamic CRF pathways [210], which could mediate the reported anxiogenic effects of chronic psychostimulant administration [204, 207, 211]. There is abundant evidence of bidirectional interactions

between sleep–wake and HPA axis activity rhythms. Sleep disturbances have been reported in adults with ADHD and include poorer sleep quality and higher nocturnal motor activity that improve after treatment with methylphenidate [212]. In healthy volunteers, stimulants seem to impair subjective ratings of sleep and increase early morning alertness [213, 214]. Although stimulants improve sleep–wake deficits in children with ADHD, the long-term consequence of chronic stimulant treatment on sleep–wake rhythms has not been established.

Sensitization to psychostimulants has been demonstrated in nonhuman primates, but studies to demonstrate sensitization in humans have yielded equivocal results. Rhesus monkeys trained to self-administer cocaine showed an augmented response to cocaine-induced elevations in striatal extracellular dopamine that emerged over a two-year period of drug exposure [215]. Chronic amphetamine exposure in nonhuman primates also induced a pattern of behavioral response that resembled the positive-like symptoms of schizophrenic humans [216]. Negative-like symptoms have also been observed in nonhuman primates following chronic amphetamine treatment [217]. More recently, a longitudinal study in rhesus monkeys exposed to repeated, escalating doses of amphetamine documented enhanced behavioral responses to subsequent acute low-dose amphetamine challenges [218]. Moreover, the enhanced behavioral responses to amphetamine challenge were evident up to 28 months postwithdrawal from chronic treatment. Several human studies in normal volunteers with no history of prior stimulant use reported evidence of sensitization to psychological (energy level and mood) and physiological (eye-blink rates) measures following two or three daily doses of amphetamine [219–221]. The outcome measures demonstrated enhanced increases following the last amphetamine dose compared to the first dose, suggesting that behavioral sensitization can be documented in human subjects. However, studies conducted in experienced stimulant users have not found evidence of sensitization. Experienced cocaine users failed to show sensitization after one or four prior cocaine exposures [222, 223]. Similarly, subjects with histories of stimulant use failed to show sensitization to oral amphetamine or methamphetamine [224, 225]. Repeated amphetamine challenges in patients with first-episode manic or schizophrenic psychosis also failed to induce sensitization [226].

There is legitimate concern that stimulant treatment during adolescence could have significant and enduring effects on reward processes relevant to mood regulation and risk for drug abuse. Preclinical studies have clearly documented that stimulants can have profound and long-lasting behavioral and neurobiological effects [91, 227]. Repeated exposure to stimulants in rodents reliably produces sensitization to their locomotor stimulant effects [228, 229] and can induce cross-sensitization with different classes of stimulant drugs [230]. Locomotor sensitization has been reported for low-dose stimulant administration intended to model therapeutic dosing [229]. Importantly, repeated dosing protocols that produce locomotor sensitization in rats can enhance the reinforcing properties of stimulants [231–234]. Once established, these behavioral and associated neurobiological changes can be remarkably stable and enduring [91, 235, 236]. Collectively, the results of laboratory studies in rodents raise significant concerns that prior exposure to stimulants, including those prescribed for the treatment of ADHD, may increase vulnerability to drug abuse in humans [237]. However, this area of investigation has received inadequate attention in human subjects and has not been approached with the experimental control and rigor afforded in animal studies. While ADHD is prevalent

in treatment-seeking substance abusers [238], clinical studies have not provided direct support for concerns that have emerged from preclinical studies. On the contrary, recent reports suggest the possibility of reduced risk for substance disorders in children with ADHD who received therapeutic administration of stimulants such as methylphenidate [239, 240]. There is an obvious need to develop clinically relevant animal models that effectively extrapolate to the human condition.

Efforts to define the long-term neurobiological consequence of psychostimulant administration have focused primarily on the dopaminergic system and have yielded inconsistent results. For example, cocaine exposure has been reported to increase, decrease, or have no effect on dopamine transporter density in rodents [241–247]. Similarly, chronic cocaine administration in rodents has been reported to increase, decrease, or have no effect on dopamine D₁ or D₂ receptor density [248–251]. The equivocal results likely reflect different dosing regimens and withdrawal periods as well as the use of noncontingent drug administration protocols that do not model voluntary drug use. Active drug self-administration protocols and periods of drug abstinence can have profound influences on neuroadaptive changes in dopamine systems [252]. Accordingly, a more consistent picture has emerged from nonhuman primate studies of cocaine self-administration. For example, in rhesus monkeys trained to self-administer cocaine intravenous for 5 days, 3.3 months, or 1.5 years, initial exposure leads to moderate decreases in dopamine transporter density in the striatum, as determined postmortem with quantitative autoradiography [253]. However, longer exposure resulted in increased striatal dopamine transporter density that was most pronounced in the ventral striatum at the level of the nucleus accumbens. Importantly, the increases in dopamine transporter binding observed after long-term cocaine self-administration in nonhuman primates correspond closely to increases observed in postmortem tissue of human cocaine addicts [254, 255]. In related studies, rhesus monkeys trained to self-administer cocaine on a daily basis over 18–22 months showed lower dopamine D₁ binding density as determined postmortem with quantitative autoradiography [256]. The effects were most pronounced in regions of the striatum where the nucleus accumbens is most fully developed. In parallel studies using the same dosing schedule and quantitative autoradiography, dopamine D₂ binding density was lower in all regions of the striatum rostral to the anterior commissure [257]. Collectively, these drug-induced changes in the status of the dopamine system may contribute to the development of dependence associated with long-term psychostimulant use.

Functional neuroimaging techniques have been used effectively in humans to characterize the long-term consequences of stimulant exposure in the context of drug abuse. Compared to controls, detoxified cocaine abusers had a marked decrease in dopamine release as measured by methylphenidate-induced decreases in striatal [¹¹C]raclopride binding [34]. The self-reports of a “high” induced by methylphenidate were also less intense in cocaine abusers. The decrease in dopamine release in the striatum has been hypothesized to underlie the decrease in sensitivity to natural reinforcers in drug abusers [258, 259]. The density of the dopamine transporter and receptors in humans has also been evaluated with positron emission tomography (PET) imaging studies. In cocaine abusers, dopamine transporter density appears to be elevated shortly after cocaine abstinence but then to normalize with long-term detoxification [260]. In contrast, PET studies characterizing dopamine D₂ receptors have reliably documented long-lasting decreases in D₂ receptor density in stimulant

abusers [261]. The reduction in D₂ receptor function coupled with dysfunctional dopamine release may further decrease sensitivity of reward circuits to stimulation by natural rewards and increase the risk for drug taking [262]. Lastly, regional brain glucose metabolism measured by FDG uptake has been characterized in conjunction with dopamine D₂ receptors [263, 264]. Reductions in striatal D₂ receptors were associated with decreased metabolic activity in the orbital frontal cortex and anterior cingulate cortex in detoxified individuals. In contrast, the orbital frontal cortex was hypermetabolic in active cocaine abusers [265]. Collectively, these findings observed in stimulant abusers document significant dysregulation of dopamine systems that are reflected in brain metabolic changes in areas involved in reward circuitry. Unfortunately, such well-designed clinical studies have not been conducted in the context of stimulant use for therapeutic purposes. However, therapeutic doses of methylphenidate block dopamine transporter function and increase extracellular dopamine [266, 267]. There is also a positive correlation between clinical improvement and reduction in dopamine transporter density in the basal ganglia following methylphenidate treatment [268]. Functional magnetic resonance imaging studies suggest that methylphenidate increases frontal cortical activity in children with ADHD [269], while PET imaging studies suggest that methylphenidate modulates brain regions associated with motor function in adults with ADHD [270]. Earlier PET studies using FDG in adults with ADHD found more limited brain metabolic effects following acute administration of *d*-amphetamine [271] and following chronic administration of *d*-amphetamine or methylphenidate [272]. Clearly, there is a need to conduct well-controlled laboratory studies to document the long-term consequences of low-dose stimulant exposure on dopaminergic function and brain metabolism.

Although significant attention has been focused on the dysregulation of the dopaminergic system, it should be emphasized that chronic exposure to stimulants can have long-term neurobiological effects on numerous neurotransmitter systems. Notably, enduring changes in glutamatergic function have been associated with repeated administration of psychostimulants. For example, basal extracellular levels of glutamate in the nucleus accumbens are decreased in rats with a history of repeated cocaine exposure [88] and there is a corresponding augmentation of cocaine-induced increases in glutamate [88, 273]. Others have reported a reduction in signaling through group I and group II metabotropic glutamate receptors [101, 274] and a reduction in sensitivity of α -amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) glutamate receptors to electrical stimulation of the prefrontal cortex [275]. An enhanced inhibitory effect of dopamine on excitatory AMPA currents has also been reported [276]. The apparent downregulation of presynaptic and postsynaptic glutamate transmission following repeated cocaine exposure has been linked to cocaine-induced reinstatement of extinguished self-administration behavior and may have direct relevance toward understanding relapse to stimulant use in humans [99, 104].

There is evidence that GABAergic function is altered following chronic cocaine administration. An increase in benzodiazepine receptor binding was observed in the striatum and amygdala of rats up to 40 days after repeated cocaine administration was discontinued [277]. A sensitized behavioral response to systemically administered diazepam was also observed following the same dosing regimen [278]. These findings suggest that chronic cocaine exposure can produce alterations in GABAergic

mechanisms that may mediate aspects of drug withdrawal. Long-term alterations in the 5-HT system have also been reported. Chronic exposure to cocaine enhanced sensitivity of 5-HT_{1A} receptors to inhibit GABAergic medium spiny neurons of the striatum [279] and reduced 5-HT concentrations in the frontal cortex [280] in rats. However, a postmortem study of human cocaine users documented higher 5-HT levels in the frontal cortex compared to matched controls [281]. Dysregulation of the noradrenergic systems may also be associated with chronic cocaine exposure. Altered noradrenergic tone was observed during cocaine withdrawal in human cocaine abusers [282], and chronic cocaine self-administration in nonhuman primates upregulated the norepinephrine transporter and decreased cerebral metabolism in the bed nucleus stria terminalis, a brain region that plays a key role in cocaine withdrawal and stress-induced reinstatement of extinguished self-administration behavior [283]. Although psychostimulants do not directly interact with opiate receptors, chronic psychostimulant exposure can influence endogenous opiate systems. For example, chronic cocaine administration increased μ - and δ -opioid receptors in several rat brain regions [284]. Downregulation of κ -opioid receptors in both the nucleus accumbens and the striatum was observed after chronic administration of cocaine and amphetamine in one study [285], but no changes in κ -opioid receptors were observed after chronic administration of cocaine in another study [284]. However, postmortem brains from fatal cocaine overdose victims showed increased κ -opioid receptor binding in limbic areas [286]. Similarly, PET neuroimaging in human cocaine users showed increased μ -opioid receptor binding that correlated with self-reported cocaine craving [287].

16.3.2 Signal Transduction Mechanisms and Gene Expression

In addition to regulation of ion channels, neurotransmitters regulate virtually all progresses that occur in neurons, including gene expression. Most of the effects of neurotransmitters on target neurons are achieved through biochemical cascades of intracellular messengers. Intracellular messengers are comprised of G proteins [guanosine triphosphate (GTP) binding membrane proteins], second messengers [such as cyclic adenosine monophosphate (cAMP) and Ca^{2+}], and protein phosphoregulators [288, 289]. Monoamine receptors are coupled to G proteins which regulate adenylyl cyclase activity to modulate the second messenger cAMP. The function of cAMP is to regulate the activity of protein kinases, phospholipases, and other intracellular enzymes. In turn, the enzymes regulate a variety of intracellular processes, including gene transcription that is regulated by transcription factors. Thus, the regulation of neurotransmitter signal transduction mechanisms and changes in gene transcription and protein synthesis can alter the number and type of receptors in target neurons as well as the functional activity of intracellular systems [290]. In recent years, significant advances in molecular biology have identified important drug-induced changes in neurobiology that may play a fundamental role in the transition to addiction.

The most extensively characterized signal transduction pathways activated by psychostimulants are those associated with dopamine receptor activation. The majority of research to date has focused on the VTA and nucleus accumbens [291]. Chronic administration of cocaine upregulates the cAMP pathway in the nucleus accumbens [292]. Cocaine and amphetamine also upregulate the transcription factor

cAMP response element binding (CREB) protein in the nucleus accumbens [293, 294]. Convincing evidence suggests that these neuroadaptations can decrease sensitivity to the rewarding effects of psychostimulants and may impair the general reward system resulting in an amotivational, depressed-like state [293, 295, 296].

Acute administration of psychostimulants rapidly activates several immediate early genes in the rat brain, including *c-fos* and *c-jun* [236, 297]. The protein products of these genes function as nuclear transcription factors that regulate gene expression. Chronic exposure to stimulant can lead to tolerance of the gene activation effect and a downregulation of gene products. For example, chronic administration of cocaine significantly reduced the activity of subsequent drug exposure to induce *c-fos* and other *fos* proteins in rats [298]. Moreover, there was an accumulation of *fos*-related antigens, including the transcription factor Δ FosB [299]. Importantly, enhanced Δ FosB expression in the nucleus accumbens and dorsal striatum is associated with sensitization to the locomotor and reinforcing effects of cocaine. Overexpression of Δ FosB increased sensitivity to the locomotor stimulant and rewarding effects of cocaine and increased cocaine self-administration [300, 301]. Due to the extraordinary stability of Δ FosB, it could conceivably sustain these types of behavioral changes for weeks or months after the last drug exposure. Hence, it may serve as a molecular switch to support the initiation and maintenance of drug dependence [291].

Finally, acute administration of psychostimulants in rodents rapidly induces cocaine- and amphetamine-regulated transcript (CART) peptides in brain regions associated with reward systems, including the VTA, ventral pallidum, amygdala, lateral hypothalamus, and nucleus accumbens [302, 303]. Hence, CART is anatomically positioned to regulate mesolimbic dopamine function, and there is evidence that CART may play a role in the behavioral effects of psychostimulants. For example, administration of CART into mesolimbic regions can induce behavioral effects similar to those observed for psychostimulants. Direct injection of CART into the VTA of rats produced modest increases in locomotor activity and promoted conditioned place preference [304]. Intra-VTA injection of CART also induced modest but significant elevations in extracellular dopamine [302]. However, when coadministered with cocaine or amphetamine, CART attenuated drug-induced increases in locomotor activity [305, 306]. This functional antagonism suggests that CART peptides may be considered as potential targets for medication development to treat psychostimulant abuse [302]. It is interesting to note that CART messenger RNA (mRNA) levels were increased in the VTA of cocaine overdose victims [307, 308].

16.4 MEDICATION DEVELOPMENT

There is a growing appreciation that drug addiction is a chronic relapsing disorder with a biological basis. Significant advances in the understanding of neurobiological mechanisms underlying drug abuse and dependence have guided pharmacological treatment strategies to improve clinical outcome. Considerable effort has been directed toward the development of effective medications for substance abuse disorders and has led to useful pharmacological interventions. Notably, methadone has been an effective medication and adjunct in the treatment of heroin abuse for many years [309, 310], nicotine replacement has been effective in smoking cessation [311], and naltrexone has documented efficacy in the treatment of alcoholism [312,

313]. During the past two decades, psychostimulant addiction has been a major focus of multidisciplinary research efforts, including molecular approaches, preclinical behavioral studies, and clinical trials. However, no suitable medication has been approved for the treatment of stimulant use disorders [314, 315]. It should be noted that the vast majority of clinical research has focused on cocaine rather than other psychostimulants such as amphetamines and methylphenidate. The extent to which outcomes related to cocaine addiction can be extended to other psychostimulants remains unclear [316]. There are multiple pharmacological approaches in the treatment of cocaine abuse and dependence, including (1) functional antagonist treatments which block the euphoric effects of cocaine and extinguish illicit drug use; (2) functional agonist treatments which replace some of the pharmacological effects of cocaine, thereby stabilizing neurochemistry and behavior; and (3) treatments that attenuate symptoms of cocaine toxicity or withdrawal [314, 316]. Numerous medications have been evaluated for treatment of cocaine dependence that include a wide range of pharmacological targets. Reviews of the clinical literature have reported no significant benefit from antidepressants or dopamine agonists for cocaine dependence [317, 318]. Antagonist strategies designed to block the euphoric or positive effects of psychostimulants with antipsychotic medications have included risperidone [319], flupenthixol [320], and olanzapine [321] and have yielded negative clinical outcome largely due to poor compliance and treatment retention. Several novel approaches that have shown some clinical promise include disulfiram, a well-established medication for treatment of alcoholism [322–324], and GABA_B receptor agonists [114]. A recent review also reported promising results for agonist-like stimulant medications in the treatment of cocaine and amphetamine dependence [314].

Tricyclic antidepressants are the best-characterized class of medications for the treatment of cocaine dependence. Desipramine was the first medication reported to be effective in an outpatient, controlled clinical trial. An initial meta-analysis found desipramine to be effective in reducing relapse to cocaine use [325], but subsequent clinical trials did not confirm its effectiveness [326, 327] or found it effective only for limited periods [328]. Based on pharmacological mechanisms, there is no convincing rationale for selecting desipramine over other tricyclic antidepressants [316]. Initial human laboratory studies with the selective serotonin reuptake inhibitor fluoxetine were encouraging. A four-week inpatient study in healthy volunteers found that fluoxetine significantly decreased subjective ratings of cocaine-induced positive mood effects [329]. However, controlled clinical trials with fluoxetine have not documented significant advantages over placebo [330, 331]. Similarly, clinical effectiveness has not been documented for the antidepressants bupropion [332] and nefazodone [333].

Agonist medications share pharmacological mechanisms of action with the abused drug, thereby producing some common neurochemical effects. Agonist medications for treatment of cocaine dependence have included direct dopamine receptor agonists and indirect dopamine receptor agonists. Preclinical studies in nonhuman primates involving chronic treatment with direct dopamine receptor agonists on cocaine self-administration have not yielded encouraging results. For example, chronic treatments with full and partial dopamine D₁ receptor agonists produced nonselective decreases in cocaine- and food-maintained responding in squirrel monkeys [334] or moderately selective decreases in cocaine-maintained responding in rhesus monkeys [335]. The D₂/D₃ receptor agonist quinpirole failed to reliably suppress cocaine self-administration at doses that produced overt toxicity in squirrel monkeys

[336]. Clinical studies with dopamine receptor agonists have also been disappointing. For example, bromocriptine is a D₂-like receptor agonists and a partial D₁-like receptor agonist used mainly in the treatment of Parkinson's disease. In a human laboratory study, pretreatment with bromocriptine prior to cocaine administration had no effect on cocaine-induced euphoria [337]. Moreover, the results of outpatient clinical trials with bromocriptine were inconclusive [316]. A recent eight-week open-label study with combined bupropion and bromocriptine in cocaine-dependent subjects did not find improvement based on cocaine-positive urine screens [338]. Collectively, these findings do not support the use of bromocriptine as a pharmacotherapy for cocaine dependence.

Studies evaluating the effects of indirect dopamine agonists have yielded mixed but more encouraging results. Mazindol, a dopamine and norepinephrine reuptake inhibitor used in the treatment of obesity, did not alter the subjective effects of cocaine in a human laboratory study [339]. Moreover, in a six-week, placebo-controlled study in cocaine-dependent subjects, mazindol did not differ from placebo in reducing cocaine use and mazindol treatment was not well tolerated [340]. Methylphenidate, a dopamine and norepinephrine reuptake inhibitor used in the treatment of ADHD and narcolepsy, was well tolerated and led to better retention than placebo but was not effective in reducing cocaine use in cocaine-dependent subjects [341]. In a separate study in cocaine-dependent subjects with ADHD, there was no significant reduction in cocaine use [342]. However, clinical studies with the indirect dopamine agonist disulfiram have been more encouraging. Disulfiram blocks the conversion of dopamine to norepinephrine by inhibiting the enzyme dopamine β -hydroxylase, thereby increasing brain dopamine concentrations. Two controlled clinical trials in cocaine addicts that were not alcoholics found disulfiram to be significantly better than placebo in promoting cocaine abstinence [322, 323]. A recent outpatient study in cocaine-dependent subjects replicated these earlier findings, showing that disulfiram reduced cocaine use more than placebo did [324]. Collectively the results suggest that disulfiram may be effective in treating cocaine addicts, including those who are not alcoholic.

There is growing support from preclinical studies in nonhuman primates and recent clinical studies for the use of stimulant medications in the treatment of cocaine dependence [341, 343–346]. A number of studies in nonhuman primates provide evidence that dopamine transporter inhibitors can effectively attenuate cocaine self-administration [21, 23, 37, 38, 347]. Hence, the development of compounds that target the dopamine transporter represents a logical approach for the pharmacological treatment of cocaine dependence. Similarly, chronic treatment with the nonselective monoamine releaser dextroamphetamine produced sustained and selective decreases in cocaine self-administration in rhesus monkeys [344, 345]. A possible limitation to the use of dopamine transport inhibitors and monoamine releasers as medications for the treatment of cocaine dependence is their potential for abuse, given their documented reinforcing effects. However, recent evidence suggests that the reinforcing effectiveness of dopamine transporter inhibitors may be limited by dual actions at the dopamine and serotonin transporters. For example, a cocaine analog with high affinity at dopamine and serotonin transporters was not reliably self-administered when substituted for cocaine, yet suppressed cocaine self-administered at low levels of dopamine transporter occupancy [38]. Similarly, monoamine-releasing agents exhibited decreasing reinforcing efficacy when the serotonin-releasing potency was

increased relative to the dopamine-releasing potency [46]. Accordingly, combined actions at dopamine and serotonin transporters may enhance effectiveness in reducing cocaine use and limit the abuse liability of the medication. Importantly, compelling data have emerged from clinical research supporting indirect agonist pharmacotherapy for stimulant abuse and dependence. Well-designed, placebo-controlled clinical trials in cocaine-dependent subjects found that sustained-released dextroamphetamine was better than placebo at reducing cocaine intake [314].

Medications that target glutamatergic function are reasonable candidates given the involvement of glutamatergic circuits in reward-related brain regions and evidence of cocaine-induced dysregulation of glutamate function [348]. Modafinil, recently approved for the treatment of narcolepsy, enhances glutamate function via unidentified mechanisms that induce increases in glutamate synthesis and striatal glutamate brain levels [349]. Interestingly, modafinil has clinical effects in nondependent subjects that are opposite to the cocaine withdrawal syndrome [350]. In patients with severe cocaine withdrawal symptoms, modafinil treatment resulted in higher rates of cocaine abstinence and treatment retention. In a separate study, the subjective effects of cocaine administration in cocaine-dependent subjects were significantly reduced [351]. Modafinil was well tolerated in both studies and is currently being investigated for treatment of cocaine dependence in large, controlled clinical studies.

Recently, the GABAergic system has received significant attention as a potential target for the pharmacological treatment of cocaine dependence [315]. For example, baclofen is an antispasticity agent that is a nonselective GABA_B agonist. In a placebo-controlled study in cocaine-dependent subjects, baclofen treatment enhanced cocaine abstinence compared to placebo [352]. Tiagabine is an antiepileptic medication that increases synaptic levels of GABA by inhibiting GABA transporters. A placebo-controlled pilot study in opioid-dependent patients maintained on methadone reported that tiagabine attenuated cocaine use [353]. Topiramate is another antiepileptic medication that potentiates GABAergic transmission, but it has a complex pharmacology that includes antagonism of AMPA/kainate glutamate receptors [354]. In a recent placebo-controlled pilot study in cocaine-dependent subjects, topiramate treatment enhanced cocaine abstinence [355]. Collectively, these initial studies suggest that the GABAergic systems may be a useful pharmacological target for cocaine medication development, although additional, larger scale clinical trials are clearly warranted.

16.5 SUMMARY

The abuse liability of psychostimulants is well established and represents a significant public health concern. Currently, no effective pharmacotherapy for psychostimulant abuse has demonstrated efficacy for long-term use. A better understanding of the neuropharmacological effects of cocaine and related psychostimulants has supported efforts to develop and improve useful pharmacotherapies for psychostimulant use and dependence. An extensive literature documents the critical importance of the monoamines in the behavioral pharmacology and addictive properties of psychostimulants. In particular, dopamine plays a primary role in their reinforcing effects and abuse liability. The relevance of the dopamine transporter in the reinforcing

effects of cocaine is supported by numerous preclinical studies of drug self-administration and, more recently, by nonhuman primate and human neuroimaging studies. Also, a growing literature indicates that the serotonergic and noradrenergic systems can effectively modulate the neurochemical and behavioral effects of cocaine and amphetamine. Similarly, cortical glutamatergic systems provide important regulation of dopamine function, and GABAergic systems provide inhibitory neuromodulation of monoaminergic and glutamatergic function. Psychostimulants also activate the HPA axis and thereby engage neuroendocrine systems linked to stress reactivity. Lastly, endogenous neuropeptide systems appear to play an important role in the neuropharmacology and addictive properties of psychostimulants. Repeated exposure to psychostimulants can lead to robust and enduring changes in all of these neurobiological substrates, resulting in altered sensitivity to acute drug effects on neurochemistry and behavior as well as dysregulation of brain function linked to dependence and addiction. Recent approaches in medication development to treat psychostimulant abuse and dependence have focused largely on these well-established neurobiological mechanisms with some degree of success. In particular, functional agonist treatments may be used effectively to stabilize neurochemistry and behavior. Similarly, medications that target glutamatergic and GABAergic function are reasonable candidates that have received significant attention, and some have demonstrated effectiveness in attenuating cocaine use and enhancing cocaine abstinence. However, these encouraging results will require additional clinical studies in order to identify safe and efficacious pharmacotherapies.

17.1 MDMA

17.1.1 Introduction

Gary Henderson, a pharmacist from the University of California, first coined the term “designer drugs” in the 1960s. Its purpose was to encompass substances of synthetic origin which were structurally and pharmacologically similar to existing substances (widely used illegal drugs) but which, due to their chemical novelty, had not been specifically listed and therefore escaped legal control. One group to appear on the scene is the methylenedioxy derivatives of amphetamine and methamphetamine, and of these, perhaps the best known and probably one of the most widely abused member is 3,4-methylenedioxymethamphetamine (MDMA), popularly known as “Ecstasy.”

The first recorded mention of the compound is in a German patent filed by E. Merck in 1912 and granted in 1914, where it appears as a possible precursor of pharmacologically active compounds. The 1980s saw the rapid establishment of MDMA as a recreational drug of abuse. It became popular with North American university students among whom it came to be known under a number of different names: XTC, Adam, MDMA, M&M.

Concurrently, low-dose MDMA [75–175 mg, by mouth (p.o.)] was being used as an adjuvant in psychotherapy due to the apparent ability of the drug to reduce anxiety and psychological defense barriers, increase self-confidence, and facilitate communication between therapist and patient.

In 1985, the U.S. Drug Enforcement Administration (DEA) placed MDMA in Schedule I of the Controlled Substances Act due to its high potential for abuse, lack of clinical application, disagreement among experts as to its safety under medical supervision, and evidence that 3,4-methylenedioxyamphetamine (MDA), a related compound and principal metabolite of the drug, produced degeneration of serotonergic terminals in rat brain.

The drug is taken orally in the form of tablets and generally consumed at weekends, often at dance clubs, or “raves.” Ecstasy tablets are available in a wide variety of colors, shapes, and sizes, each decorated with a different design or logo. It produces a series of subjective symptoms and sensations among which the most frequent include an increase in empathy, that is, a sense of closeness to other people, an emotional opening up, an increased ability and willingness to communicate, a reduction in negative thoughts and inhibitions, a heightened sense of perception of sound, color, and touch, an increase in locomotor activity, insomnia, and an increase in alertness. These effects appear in the first 20–60 min after a single dose, reaching a maximal effect after 60–90 min and lasting 3–5 h.

17.1.2 Reinforcing Properties

There have been several studies on the rewarding properties of MDMA, and these studies generally implicate dopamine in the actions of the drug. Systemic MDMA administration has been shown to increase extracellular dopamine in the mesolimbic forebrain, namely the nucleus accumbens (NAc) [1–3]. The NAc is responsible for the incentive motivational properties of most drugs of abuse, and the rewarding effects of MDMA have been shown using the appropriate paradigms. Thus, rats treated with MDMA developed a positive and dose-dependent response in the conditioned place

preference (CPP) test [2, 4–6]. Since CPP is believed to be a measure of appetitive behavior, where the animal associates contextual cues with either a positive or negative feeling produced by the drug, these results provide direct evidence of the rewarding properties of MDMA in rats. A rewarding effect of MDMA has also been shown in the self-stimulation paradigm in rats [7], where MDMA lowers the reward threshold of electrical stimulation, and in the drug self-administration test in rats [8, 9] and baboons [10]. The locomotor hyperactivity observed after MDMA injection is also consistent with this drug exerting a positive rewarding effect [11, 12]. In order to determine whether dopaminergic mechanisms mediate the reinforcing effects of MDMA, Daniela and coinvestigators [9] have evaluated the effects of the D₁ receptor antagonist 7-chloro-8-hydroxy-3-methyl-1-phenyl-2,3,4,5-tetrahydro-1H-3-benzazepine hydrochloride (SCH 23390) on MDMA self-administration and compared them to the effects on MDMA-induced hyperactivity. SCH 23390 pretreatment produced a dose-dependent decrease in MDMA-induced hyperactivity and a rightward shift in the dose-response curve for MDMA self-administration. These data indicate that dopamine plays a key role in the hyperactivity that follows MDMA injection and suggest that MDMA self-administration, like the self-administration of other drugs of abuse, is dependent on the activation of dopaminergic substrates.

Recently, it has been suggested that the rewarding effects of MDMA are more pronounced at high ambient temperature and that the enthusiasm of recreational users for consuming the drug in hot environments might not be coincidental. It has been shown that an elevation of ambient room temperature enhanced the prosocial effects of MDMA and the number of MDMA infusions self-administered by rats [13]. In addition, the neurochemical changes related to rewarding effects of MDMA are more pronounced when the drug is given at high ambient room temperature [14]. By means of *in vivo* microdialysis, it has been shown that elevation of ambient temperature enhances the effect induced by low and medium doses of MDMA on dopamine release in the shell of the NAc, but not the striatum, of freely moving rats. The output of serotonin (5-HT) is also enhanced in the NAc, but not the striatum, by high ambient temperature conditions. Taken together, it seems reasonable to propose that the enhanced mesolimbic dopamine release seen at high ambient temperature is responsible for the changes seen by Cornish and coinvestigators [13].

It is also possible that previous exposure to MDMA may increase the reinforcing effects of other psychostimulants such as cocaine and amphetamine. There is strong experimental evidence indicating that rats treated with MDMA subsequently develop enhanced behavioral and biochemical responses to psychomotor stimulants. Studies have shown that in animals pretreated with MDMA cocaine produces a greater increase in the extracellular levels of dopamine in the NAc than that seen in control rats [15]. If the reinforcing effect of cocaine is dependent, in part, upon increased dopamine release in the NAc, these data suggest that MDMA may increase vulnerability to cocaine abuse. Subsequently, using the appropriate paradigms, it has been shown that rats pretreated with MDMA show a significantly greater CPP response to cocaine than vehicle-treated animals [16] although this may depend on the protocol of MDMA administration since another study failed to confirm this [17]. In mice, adolescent exposure to MDMA increased hyperlocomotion and facilitated the reinstatement of cocaine-seeking behavior, as assessed by CPP after a 14-day drug-free period [18]. These results provide direct evidence of an increase in

the rewarding properties of cocaine in rats preexposed to MDMA and suggest that MDMA abuse leads to increased vulnerability to cocaine addiction and dependence. In fact, preexposure to a high dose of MDMA facilitates acquisition of cocaine self-administration in rats [19], which again confirms that MDMA preexposure sensitizes rats to the reinforcing effects of cocaine.

The effect of MDMA on the acquisition of intravenous amphetamine self-administration and the reinstatement of amphetamine-seeking behavior by either MDMA or amphetamine has been recently evaluated [20]. Preexposure to a 5-HT-depleting regimen of MDMA slows the acquisition of amphetamine self-administration but may sensitize animals to the locomotor stimulating and priming effects of MDMA on drug-seeking behavior. Therefore, it seems likely that MDMA exposure may result in an enhanced sensitivity to psychostimulants and that this is a vulnerability to relapse that may be rather long-lasting.

Consequently, and although we must be extremely cautious when extrapolating results from animals to humans, it would be reasonable to propose that MDMA users may be at greater risk of developing addiction and dependence to other psychomotor stimulants.

17.1.3 Acute Biochemical and Behavioral Effects

17.1.3.1 Monoamine Release in Brain. MDMA is an amphetamine compound, and therefore, like other compounds of this class, its primary property is the release of monoamines in the brain.

MDMA administration produces an acute rapid release of 5-HT in the rat brain. This has been demonstrated both by in vivo microdialysis [21–23] and the decreased concentration of 5-HT in cerebral tissue taken from treated animals [24–26]. These references reflect only a few of the many studies that have reported these changes. The release occurs in all the major forebrain regions [27] and is inhibited by prior administration of 5-HT selective uptake blockers such as fluoxetine [23]. MDMA-induced 5-HT release can also be demonstrated in vitro by using brain slices [28] or synaptosomal preparations [29].

MDMA is also a potent compound in inducing dopamine release, and again this has been demonstrated using in vivo microdialysis [1, 30, 31] and in vitro using cerebral tissue slices [28].

The role of the dopamine uptake site in MDMA-induced dopamine release is controversial [32], and Mehan and coinvestigators [23] have suggested that MDMA may enter the dopamine terminal primarily by diffusion rather than via the uptake carrier site.

The role of 5-HT release in inducing dopamine efflux is indicated by the fact that pretreatment with fluoxetine attenuates MDMA-induced dopamine release in the striatum [33] and administration of a 5-HT agonist will enhance dopamine release [30]. Since ritanserin attenuates MDMA-induced dopamine release [22], it is reasonable to propose that MDMA can modify dopamine release by enhancing the efflux of 5-HT, which then acts on 5-HT_{2A/2C} receptors.

While in vitro evidence suggests that MDMA can enhance norepinephrine release from brain tissue [34] and from synaptosomes [35], in vivo microdialysis data are presently lacking.

17.1.3.2 Tryptophan Hydroxylase. MDMA administration inhibits the activity of tryptophan hydroxylase in the brain [36–38] and this effect is very rapid [37]. Inhibition is still observable two weeks after a single dose of MDMA [39]. Since tryptophan hydroxylase is the rate-limiting enzyme involved in 5-HT synthesis, this indicates that a proportion of the 5-HT loss seen soon after MDMA administration may be due to hydroxylase inhibition rather than release, while the long-term decrease in cerebral 5-HT content following MDMA may be due in part to inhibition of the enzyme rather than neurotoxicity (see later).

Since MDMA has no direct inhibitory action on the enzyme *in vitro* [39], it is possible that the inhibition seen *in vivo* results from the action of an MDMA metabolite, an hypothesis supported by the finding that the MDMA quinone derivative can inactivate the enzyme [40].

17.1.3.3 Effect on Neurotransmitter Receptors and Transporters. MDMA binds to the 5-HT, dopamine, and norepinephrine transporters, although its affinity for the 5-HT site is at least 10 times higher than for the other monoamine transporter sites [41, 42].

MDMA binds with a 1–10 μM affinity for 5-HT₂, α -adrenergic, M₁ muscarinic, and H₁ histaminic sites. Other sites (including 5-HT₁) are in the 10–100 μM range while dopamine D₁ and D₂ sites are > 100 μM [42].

17.1.3.4 Effect on Body Temperature. The effect of MDMA on body temperature has been investigated extensively in experimental animals, partly because there is a clear clinical correlate.

MDMA produces a rapid hyperthermic response in rats housed in normal or warm room conditions ($\leq 20^\circ\text{C}$) with a peak of 1–2 $^\circ\text{C}$ above normal rectal temperature [43–46]. The response is dose dependent [47]. When the rats are present in a cool ambient room temperature ($< 19^\circ\text{C}$), the effect of MDMA is to produce a hypothermic response [45, 48, 49].

If the rats are in a warm environment, the MDMA-induced hyperthermia is greater than in a normal environment [48, 50] (Fig. 17.1). Furthermore, giving divided doses over several hours to mimic “binge dosing” (but with the same total dose administered) results in a greater peak response than after a single dose [50] (Fig. 17.1).

Figure 17.1 Effect of single or repeated doses (binge dosing) of MDMA (mg/kg) on peak rectal temperature increase in Dark Agouti rats housed at ambient temperature (T_a) of either 19 or 30 $^\circ\text{C}$. Doses of MDMA are shown.

The rise in rectal temperature appears to result from the action of the dopamine released by MDMA, on dopamine D₁ receptors, since the effect was antagonized by the D₁ antagonist SCH 23390, but not the D₂ antagonist remoxipride [23]. However, the hypothermia seen after MDMA is given to rats in a cool environment is dopamine D₂ receptor mediated, since remoxipride blocks the effect while SCH 23390 is without effect (Green and coinvestigators, unpublished).

Gordon and coinvestigators [51] found that the metabolic rate increased when MDMA was given to rats housed at 20°C, together with an increase in evaporative water loss. This suggests increased thermogenesis. This interpretation is supported by the fact that there is an involvement of the hypothalamic–pituitary–thyroid axis in the response [52] and crucially that β_3 adrenoceptors are involved, which indicates an action in brown adipose tissue [53]. Heat loss mechanisms do not appear to be activated immediately to compensate for the thermogenesis, since the tail temperature does not rise following MDMA [23] (the tail is a major heat loss organ in the rat [54]).

It has been known for many years that grouping mice increases the hyperthermic effect of amphetamine and increases its toxicity compared to the effect of the drug when given to individually housed animals [55]. Recently, Fantegrossi and coinvestigators [56] observed that the same phenomenon occurred when MDMA was examined in both singly housed and grouped mice. This has implications for the recreational use of MDMA in humans since the drug is primarily used in hot, crowded club conditions.

17.1.3.5 Neuroendocrine and Immune Responses following MDMA. The monoamine release by MDMA initiates neuroendocrine changes. In rats both serum corticosterone and prolactin concentrations increase after MDMA [43], with the corticosterone response lasting over 4 h and the prolactin more than 1 h. The corticosterone response was dose dependent and blocked by ketanserin, suggesting an involvement of 5-HT.

Both aldosterone and renin also increase after MDMA administration to rats, and again, the aldosterone rise appears to be induced through increased 5-HT release [57]. In vitro studies have also demonstrated MDMA-induced oxytocin and vasopressin release in hypothalamic tissue [58, 59].

Several studies have demonstrated that MDMA can alter the immune function of the rat. Leucocyte counts are reduced for several hours after MDMA, as is concanavalin A-induced lymphocyte proliferation. This suggests that the drug produces a sustained suppression of mitogen-stimulated lymphocyte proliferation as well as leucocyte count and indicates a suppression of immune function [60].

17.1.3.6 Effects on Behavior. Since MDMA releases 5-HT from the nerve ending, it is not surprising that it can produce aspects of the *serotonin behavioral syndrome* [44, 61–63]. This syndrome was first described by Grahame-Smith [64] and consists of head weaving, reciprocal forepaw treading, proptosis, piloerection, and salivation. MDMA also produces a dose-dependent increase in locomotor activity [65], which can be antagonized by N-[4-methoxy-3-(4-methyl-1-piperazinyl)]-2'-methyl-4'-(5-methyl-1,2,4-oxadiazol-3-yl) [1,1-biphenyl]-4 carboxamide hydrochloride monohydrate (GR127935), a 5-HT_{1B/1D} antagonist, but not by N-(2-[4-(2-methoxy-phenyl)-1-piperazinyl] ethyl)-N-(2-pyridinyl) cyclohexane trihydrochloride (WAY100635), a 5-HT_{1A}

antagonist. However, the work of Bankson and Cunningham [66] has emphasized the complexity of the hyperactivity response by showing the possible involvement of 5-HT_{2B/2C} receptor function. Acute MDMA administration has been examined in various tests of anxiety-like behavior and data still remain somewhat conflicting. In the elevated-plus maze test Morley and McGregor [67] found the drug to produce an anxiogenic-like effect in rats. However, in the social interaction test an anxiolytic-like effect was seen. In contrast, Bhattacharya and coinvestigators [68] observed an anxiogenic effect in both tests. Lin and coinvestigators [69] saw an anxiogenic effect in mice exposed to the elevated-plus maze following low doses of the drug but an anxiolytic effect following high-dose administration. An anxiogenic effect was also reported to occur following MDMA administration to mice when the social interaction test was used [70].

17.1.4 Long-Lasting Biochemical and Behavioral Effects: Neurotoxicity

MDMA produces a characteristic biphasic neurochemical response which can be divided into acute effects, consisting of changes in cerebral biochemistry which are reversible, and long-term effects, including biochemical and structural changes in the brain which are persistent and are considered to reflect neurotoxicity.

MDMA administration produces a marked and rapid (3–4-h) depletion of 5-HT in several brain regions [71]. There is a recovery of brain 5-HT concentration within 24 h, but this is followed within three to four days by a long-term decrease which is unequivocal and which lasts for several months [71, 72]. This second phase of monoamine loss reflects neurodegenerative changes in serotonergic nerve terminals that have occurred, and it has been demonstrated in rats, guinea pigs, and several species of nonhuman primates. In mice the response is quite different, for while MDMA also behaves as a neurotoxin, it produces a reduction in the number of dopaminergic nerve terminals in striatum but leaves 5-HT-containing neurons intact. It is worth emphasizing that neurotoxicity in mice requires repeated injection of MDMA and also higher doses than those used in rats.

17.1.4.1 Long-Term Neurochemical Changes. There is clear and unequivocal evidence for a substantial and sustained long-term neurotoxic loss of 5-HT nerve terminals in several regions of the rat brain [31, 71, 73–77]. The degeneration has been demonstrated histologically [78, 79] and biochemically and is reflected in a substantial decrease in tryptophan hydroxylase activity; a reduction in the concentration of 5-HT and its metabolite, 5-hydroxyindoleacetic acid (5-HIAA); a decrease in the density of 5-HT uptake sites labeled with [³H]paroxetine [77, 80–82]; and a reduction in the immunoreactivity of fine 5-HT axons in the neocortex, striatum, and hippocampus [78]. The dose required to induce neurotoxicity in rats is strain dependent. For example, Dark Agouti rats require a single dose (10–15 mg/kg) of MDMA to produce a clear 30–50% or greater loss in cerebral 5-HT content [47, 83] while strains such as Sprague–Dawley, Hooded-Lister, and Wistar require repeated and higher doses of MDMA (often 20 mg/kg or more) [44, 63, 84].

Although the neurotoxic potential of MDMA is well established, there is relatively little information on the fate of lesioned 5-HT neurons. Some authors have suggested that there is a substantial recovery of 5-HT function after MDMA-induced lesions in rodents [85–90]. While rats exposed to repeated administration of MDMA (10 mg/kg)

show a marked reduction (60–80%) of 5-HT transporters in the hippocampus, striatum, and cerebral cortex 2 weeks after dosing, some signs of recovery are observed in all brain areas at 16 weeks, and by 32 weeks the recovery is complete in the striatum and cerebral cortex [88]. Immunohistochemical data confirm these biochemical results and show that the recovery of 5-HT presynaptic markers is due to the regeneration of 5-HT-containing axons [79, 88]. Axonal reinnervation refers to fine 5-HT axons coming from the dorsal raphe nucleus, which are the axons selectively lesioned by MDMA [78, 91], while thicker and varicose axons coming from medial raphe nucleus are not affected by MDMA [78, 91] and do not show any evidence of collateral ramification [79]. Nevertheless, the pattern of reinnervation is anomalous, since distal brain areas such as the neocortex remain denervated while proximal areas such as the hypothalamus appear either reinnervated or hyperinnervated [92]. Together, these results confirm the plasticity of central 5-HT neurons [93, 94] and indicate that under specific conditions 5-HT neurons have recovered from the MDMA-induced damage. Nevertheless, although the effects of MDMA in rodents seem to be partially reversible, they are probably permanent in primates. Insel and coinvestigators [95] observed significant 5-HT deficits in the hippocampus, striatum, and cortex of the *Maccacus rhesus* 14 weeks after repeated administration of MDMA. Similar results have been found in the hippocampus, caudate nucleus, and frontal cortex of squirrel monkeys 18 months after dosing [96]. In a study carried out seven years after MDMA dosing, Hatzidimitriou and coinvestigators [97] found that 5-HT axon density is only 50–65% of control values in neocortical regions. These data suggest that the 5-HT axons in nonhuman primates do not recover from MDMA-induced damage, and this information is particularly significant since it could be indicative of what happens in human beings, considering that the dose given to nonhuman primates is similar to that taken by humans.

17.1.4.2 Experimental Studies with Similar Doses to that Consumed by Humans. Recreational Ecstasy users tend to believe that the doses administered to experimental animals to induce toxicity are much higher than those that they use and that the data obtained are not relevant to human use. They therefore conclude that MDMA is a safe drug. Ecstasy tablets have been reported to contain generally between 70 and 150 mg [98], which is equivalent to 1–2 mg/kg of MDMA in a 70-kg human. However, Ecstasy is often ingested repeatedly in such a way that it is frequent for an individual to consume several tablets during a weekend [99]. What is perhaps most important is the *exposure* to the drug, and measurement of plasma levels is particularly important for that assessment. However, this measurement is rarely made in experimental animals. Nevertheless, the study of Colado and coinvestigators [83] did show that a single dose of MDMA of 10 mg/kg administered to Dark Agouti rats produced a plasma level of MDMA of near 10 nmol/mL 45 min later. Similar values have been observed clinically in overdose cases. This therefore suggests that dosing schedules in rats are often producing exposure that is not markedly different from those experienced by recreational users.

Several studies have been performed modeling the doses and dosing schedules of MDMA often used by human recreational users. O'Shea and coinvestigators [47] administered MDMA to Dark Agouti rats at the dose of 4 mg/kg once or twice daily for four consecutive days. The rats were killed seven days after dosing. Once-daily injection had no effect on regional brain concentration of 5-HT and 5-HIAA, while

twice-daily administration resulted in a substantial depletion in all brain areas examined. These data thus indicate that high or frequent doses of MDMA are required to produce neurotoxic damage.

Studies giving low and repeated doses of MDMA have also been performed in nonhuman primates, and these showed that neurotoxic effects are more pronounced than those observed in rodents [100]. For example, administration of 2.5 mg/kg MDMA twice daily for four consecutive days produced 44% depletion of 5-HT in the somatosensory cortex of the monkey [101], while to obtain similar depletion in the brain of Dark Agouti rats, it is necessary to administer 4 mg/kg MDMA when following the same dosing protocol [47].

The degree of 5-HT depletion may also be dependent upon the route of administration, although data on this point are conflicting. While similar neurotoxic effects were observed in rats following oral or subcutaneous dosing [102], oral administration in monkeys seemed to be less effective than subcutaneous injection [103]. In contrast, Kleven and coinvestigators [104] obtained a more marked effect of the drug when it was given to rhesus monkeys by the intragastric route rather than subcutaneously.

A practice sometimes employed by recreational users of Ecstasy is “binge” dosing, comprising the ingestion of several doses on a single occasion [105, 106]. This type of dosing has been recently modeled by administering three doses of MDMA (2, 4, or 6 mg/kg) 3 h apart and evaluating its consequences on the long-term neurotoxic effects of MDMA when administered to rats housed either at 19°C or in a room kept at 30°C to simulate the way in which the drug is sometimes taken by human beings in a hot, dance club environment [107]. At 19°C MDMA produced a dose-dependent long-term loss of 5-HT in several brain regions with an approximate 50% loss following 3×4 mg/kg and a 65% decrease following 3×6 mg/kg. When MDMA at the dose of 4 mg/kg was injected repeatedly to rats housed at 30°C, a larger long-term 5-HT depletion (65%) than that found in rats treated at 19°C was observed, the effect being similar to that produced by the dose of 6 mg/kg given at 19°C ambient temperature.

17.1.4.3 Mechanisms of Neurotoxicity.

17.1.4.3.1 Neurotoxic Metabolite. The toxicity induced by MDMA in both rat and mouse is mediated by one or more metabolites of the drug that have been formed peripherally. Evidence for this in rats stems from the fact that central administration of MDMA does not produce reductions in the concentrations of 5-HT in various terminal fields [108–110] in spite of brain concentrations being greater than those following systemic administration of a neurotoxic dose of the drug [110]. Central administration of the MDMA did, however, produce an increase in 5-HT release in the hippocampus, and dopamine release in the striatum, similar to that produced by systemic administration [31, 110], suggesting that whereas the neurotoxic effects of the drug are produced by a peripherally formed metabolite, the acute effects are induced by the parent compound.

In contrast to that which occurs in the rat, recent studies indicate that in mice MDMA is responsible for neither the acute nor the long-term effects of the drug [111]. Intrastratial administration of MDMA does not reproduce the reduction in dopamine and the changes in 3,4-dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA) observed following systemic administration.

The lack of neurotoxicity following the central administration of the drug has led to numerous studies on the peripheral metabolism of MDMA, mostly in the rat. One

of the principal metabolites of MDMA in this species is MDA, the product of N demethylation via the CYP1A2 isoform of the cytochrome P450 monooxygenase system. This compound exhibits a similar profile but higher potency as a serotonergic neurotoxicant than MDMA and, like MDMA, is not toxic when injected directly into the brain [108]. Thus, MDA may be an intermediate product but is not the final neurotoxic metabolite.

The drug can undergo various other routes of metabolism (O demethylation, deamination, and hydroxylation) and conjugation (O methylation, O glucuronidation, and O sulfation), giving rise to 17 in vivo metabolites [112–114], several of which have been tested in vivo. None, however, has been found to produce the same pattern of toxicity as that produced by systemic MDMA. Thus, aromatic hydroxylation gives rise to 6-hydroxy-MDMA [114, 115], which is demethylated by CYP2D1 to yield 2,4,5-trihydroxymethamphetamine [112, 113], both of which have been shown to produce a different profile of toxicity to MDMA—either lack of toxic effect or toxicity of both the 5-HT and dopamine neurotransmitter systems, respectively [116, 117].

Direct demethylation of MDMA or MDA by CYP2D1 gives rise to 3,4-dihydroxymethamphetamine (HHMA; *N*-methyl- α -methyldopamine, *N*-Me- α -Me DA) and its demethylated equivalent, 3,4-dihydroxyamphetamine (HHA; α -methyldopamine, α -Me DA), which are unstable reactive catechol derivatives that may in turn form quinones that can auto-oxidize and produce free radicals. Alternatively, these catechols can undergo O methylation at position 3 or 4 of the aromatic ring to form 3-hydroxy-4-methoxy(meth)amphetamine [4-*O*-methyl- α -(methyl)dopamine, 4-*O*-Me- α -(Me) DA] or 4-hydroxy-3-methoxy(meth)amphetamine [3-*O*-methyl- α -(methyl)dopamine, 3-*O*-Me- α -(Me) DA]. Neither α -Me DA nor 3-*O*-Me- α -Me DA produce serotonergic toxicity [118].

In recent years, the glutathione-formed conjugates of the quinones that are discussed above have been suggested as possible neurotoxic metabolites of the drug [119, 120]. Thus, a putative metabolite adduct, 5-(glutathion-*S*-yl)- α -Me DA, crosses the blood–brain barrier by means of the glutathione carrier [121] and is neurotoxic to 5-HT terminals following repeated intracerebral injection [119]. Addition of a further glutathione molecule to 5-(glutathion-*S*-yl)- α -Me DA yields 2,5-(glutathion-*S*-yl)- α -Me DA, which is a more potent neurotoxin [119]. Once in the brain these compounds can be further metabolized to cysteine or acetylcysteine adducts which are more potent toxins [119, 120, 122]. Jones and coinvestigators [122] recently identified glutathione and *N*-acetyl cysteine conjugates of *N*-Me- α -Me DA in rat striatal dialysate after subcutaneous MDMA administration. Furthermore, inhibition of γ -glutamyl transpeptidase increases the toxicity produced by MDMA and MDA and the levels of the *N*-acetyl cysteine adducts in brain by increasing the pool of the thioether compounds available for transport by the glutathione carrier [121, 122].

In the mouse, no studies have been carried out on products of metabolism, although Escobedo and coinvestigators [111] found that the major compound in brain following peripheral MDMA administration is MDMA itself. This is in sharp contrast to what is observed in rats, where MDA is the major metabolite at low doses, and in humans, where HHMA predominates [123]. Further studies on the different profiles of metabolism in the rat and mouse are required in order to evaluate if these differences could account for the neurotoxic selectivity of the drug in the different animal species.

17.1.4.3.2 Oxidative Stress. There is much experimental evidence indicating that a major mechanism by which MDMA induces damage to 5-HT-containing neurons in the rat brain is by inducing an oxidative stress process [77, 124] which is ultimately reflected by an increase in lipid peroxidation in several brain areas [125]. Two factors contribute to this process, a decrease in the antioxidant capacity of the brain reflected as a reduction in vitamin E and ascorbate levels [126] and an increase in the formation of hydroxyl-free radicals [77, 127]. The use of intracerebral microdialysis has demonstrated that systemic administration of MDMA increases the formation of 2,3-dihydroxybenzoic acid (2,3-DHBA) from salicylate in hippocampal and striatal dialysates of rats and mice [77, 128–130], a conversion that only occurs in the presence of a high concentration of hydroxyl-free radicals. Administration of the hydroxyl radical scavenger α -phenyl-*N*-*tert*-butyl nitron (PBN) abolished the MDMA-induced rise in 2,3-DHBA and attenuated neurotoxic damage and did so without altering MDMA-induced hyperthermia [77, 127]. Other free-radical scavenging drugs have also been found to protect against MDMA-induced damage. Thus, administration of large doses of sodium ascorbate or L-cysteine 30 min prior to and 5 h following MDMA injection prevented the long-term depletion of 5-HT induced by MDMA [131]. Ascorbic acid administration also suppressed hydroxyl radical formation in the striatum [126]. The metabolic antioxidant α -lipoic acid injected repeatedly (up to two days after MDMA) also totally prevented the reduction in the number of 5-HT transporters observed seven days after MDMA dosing [132]. In addition to hydroxyl radicals, nitrogen-reactive species are also involved in MDMA-induced neurotoxicity. Gudelsky's team [133] found evidence for the involvement of nitric oxide in MDMA-induced serotonergic neurotoxicity. A multiple-dose regimen of MDMA produced a significant increase in levels of nitrotyrosine and nitric oxide in the striatum. Pretreatment with the neuronal nitric oxide synthase (NOS) inhibitor *S*-methyl-L-thiocitrulline (*S*-MTC) afforded neuroprotection against MDMA-induced 5-HT depletion without attenuating MDMA-induced hyperthermia. In addition, administration of NOS inhibitors, as well as a peroxynitrite decomposition catalyst, attenuated the long-term depletion of striatal 5-HT and dopamine depletion produced by the local perfusion of MDMA and malonate.

In mice there is also evidence for a key role of oxygen- and nitrogen-reactive species in the MDMA-induced neurotoxicity on dopamine neurons. Pretreatment with either of the NOS inhibitors *S*-MTC and *N*-(4-(2-((3-chlorophenyl methyl)amino)-ethyl)-phenyl) 2-thiopene carboxamidine hydrochloride (AR-R17477AR) provided significant neuroprotection against the long-lasting MDMA-induced dopamine depletion, and AR-R17477AR prevented the rise in 2,3-DHBA levels in striatal dialysates of the mice [129]. Also supporting the suggestion that free-radical formation is responsible for MDMA-induced neurotoxicity is the study in which mice fed a selenium-deficient diet showed an enhancement of the long-term dopamine depletion and, strikingly, also a long-term loss of 5-HT content in several brain areas, an effect not observed in mice maintained with a standard diet [134]. This effect is due to an impairment of the antioxidant detoxification system mediated by glutathione, as these animals also show a decrease in the activity of glutathione peroxidase and an increase in the degree of lipid peroxidation [134]. In fact, MDMA administration to mice maintained with a standard diet caused a decrease in glutathione peroxidase and superoxide dismutase activities and an increase in lipid peroxidation in several regions of mouse brain [135]. Finally, transgenic mice overexpressing CuZn superoxide dismutase have been shown

to be resistant to the neurotoxic action of MDMA [136]. A recent study by Fornai and coinvestigators [137] reported DNA oxidation and DNA single-strand breaks accompanied by increased clustering of heat shock protein-70 (HSP-70) in the nucleus close to chromatin filaments in the substantia nigra and striatum of mice seven days following repeated MDMA administration. The presence of ubiquitin-positive inclusion bodies has also been reported. These findings suggest that MDMA-induced oxidation involves neuronal cell bodies and extends to the nucleus of neurons.

The source of free-radical formation is controversial. There are data supporting a role for extracellular dopamine in producing free radicals and neurotoxic damage. However, other data fail to support this contention. According to the first hypothesis, dopamine, released massively after MDMA administration, is transported into the 5-HT-depleted terminals and deaminated by monoamine oxidase type B (MAO_B), resulting in the production of hydrogen peroxide and hydroxyl free radicals [128, 138]. This hypothesis fails to demonstrate why MDMA produces damage in brain areas with little dopaminergic innervation such as the hippocampus, where the reduction in several serotonergic parameters is even more pronounced and persistent than that detected in striatum. In addition, there are data indicating that administration of dopamine precursor 3,4-dihydroxy-L-phenylalanine (L-DOPA), while enhancing the MDMA-induced dopamine release in the striatal dialysate, nevertheless fails to alter the subsequent neurodegeneration in this region [31].

Free-radical formation is increased by the acute hyperthermia produced by MDMA administration, and the rise in 2,3-DHBA levels in cerebral dialysate was markedly inhibited when the hyperthermic response was prevented. This result provides a plausible explanation as to why hypothermia or normothermia is neuroprotective against MDMA-induced damage and why hypothermia is neuroprotective against other forms of neurodegeneration such as that produced by transitory cerebral ischemia [139, 140]. However, although hyperthermia markedly enhances free-radical production, neurodegeneration can occur in normothermic animals [47], so hyperthermia is not an absolute requirement for the expression of the neurotoxic damage.

The 5-HT nerve endings are the site of the enhanced free-radical formation since a prior 5-HT lesion (produced by pretreatment with fenfluramine) prevented the MDMA-induced rise in free-radical formation [77]. This proposal was supported by the subsequent study by Shankaran and coinvestigators [141], who found that fluoxetine attenuated the MDMA-induced free-radical production. This indicates that free-radical production occurs following the transport of MDMA or a neurotoxic metabolite into the 5-HT nerve terminal by activation of the 5-HT transporter.

17.1.4.3.3 Hyperthermia. In addition to being an immediate risk factor of exposure to MDMA, the drug-induced hyperthermia plays an important role in the development of neurotoxicity in experimental animals, and numerous studies have shown that the hyperthermic reaction following MDMA, although not essential, does modulate the degree of long-term damage. Thus, a close correlation has been found between the hyperthermic response and the degree of neurotoxicity in rats [48]. Animals maintained at an elevated room temperature (26–33°C) have an augmented hyperthermic response and show a greater degree of neurotoxicity [107, 142, 143]. In contrast, physical and pharmacological modifications that either attenuate or prevent the hyperthermic reaction induced by the drug attenuate or prevent the

neurotoxic effect. Thus, the administration of MDMA to rats maintained at low ambient temperature (10°C) prevents the hyperthermic response and either attenuates or eliminates the long-term serotonergic toxicity [142, 144].

A similar observation has been made in the mouse where administration of the drug to mice at an ambient temperature of 15°C reduced body temperature by approximately 2°C and blocked the long-term dopaminergic damage [145]. Furthermore, restraint, which protects mice from the neurotoxic effects of MDMA, is thought to mediate its effect by lowering body temperature [146].

Further evidence for the importance of the hyperthermic response in the degree of neurotoxicity derives from neuroprotection studies. A number of compounds, including haloperidol, pentobarbital, reserpine, α -methyl dopamine, dizocilpine, and ketanserin, have been shown to be protective against the neurotoxic effects of MDMA in the rat because they prevent the hyperthermic response to the drug or produce hypothermia [31, 46, 143, 147, 148]. The protective effect of these compounds disappears when the temperature of the animals is kept similar to that in animals treated with just MDMA. Clomethiazole appears to possess a partial protective action which is independent of its temperature-lowering effects [149].

Despite the preceding evidence on the correlation between the magnitude of the acute hyperthermia and the degree of neurotoxic damage, MDMA may also cause neurotoxic damage in the absence of a hyperthermic response. The repeated administration of low-dose MDMA (4 mg/kg twice daily for four days) produced a substantial neurotoxic effect in Dark Agouti rats but caused only a slight increase in temperature above saline-treated controls after the first dose. This increase in temperature after the initial dose was not sufficient in itself to produce a neurotoxic effect [47]. In addition, high doses of MDMA have also been reported to produce serotonergic toxicity in the absence of a hyperthermic response [142].

Taken together, this evidence indicates that hyperthermia has an important modulatory role but is not an essential factor in the neurotoxicity induced by the drug. Other factors such as high doses or increased frequency of dosing are also important factors and may overcome a lack of hyperthermic response to produce neurotoxicity.

17.1.4.3.4 Monoaminergic Transporter. Evidence indicating a role of the 5-HT transporter in the long-term damage on 5-HT nerve terminals induced by MDMA is based on the findings that 5-HT transporter inhibitors prevent the long-lasting loss of 5-HT brain concentration. The first study showing the neuroprotective effect of fluoxetine against MDMA neurotoxicity is the report of Schmidt [71]. This study shows that coadministration of this selective 5-HT uptake inhibitor completely blocked the reduction in cortical 5-HT concentrations one week after MDMA. Administration of fluoxetine at various times after MDMA revealed that the long-term effects of the drug could be partially blocked by the uptake inhibitor as long as 6 h after drug administration. The neuroprotective effect of fluoxetine administered concurrently with MDMA was confirmed subsequently [46, 82, 141] and extended to fluvoxamine [82] (Fig. 17.2). Neither fluoxetine nor fluvoxamine altered MDMA-induced acute hyperthermic response [46, 82]. Fluoxetine continued to provide total protection when given up to four days before MDMA (Fig. 17.2), but fluvoxamine only produced neuroprotection when coadministered with MDMA (Fig. 17.2). This longer-lasting neuroprotective effect of fluoxetine might be due to the persistent

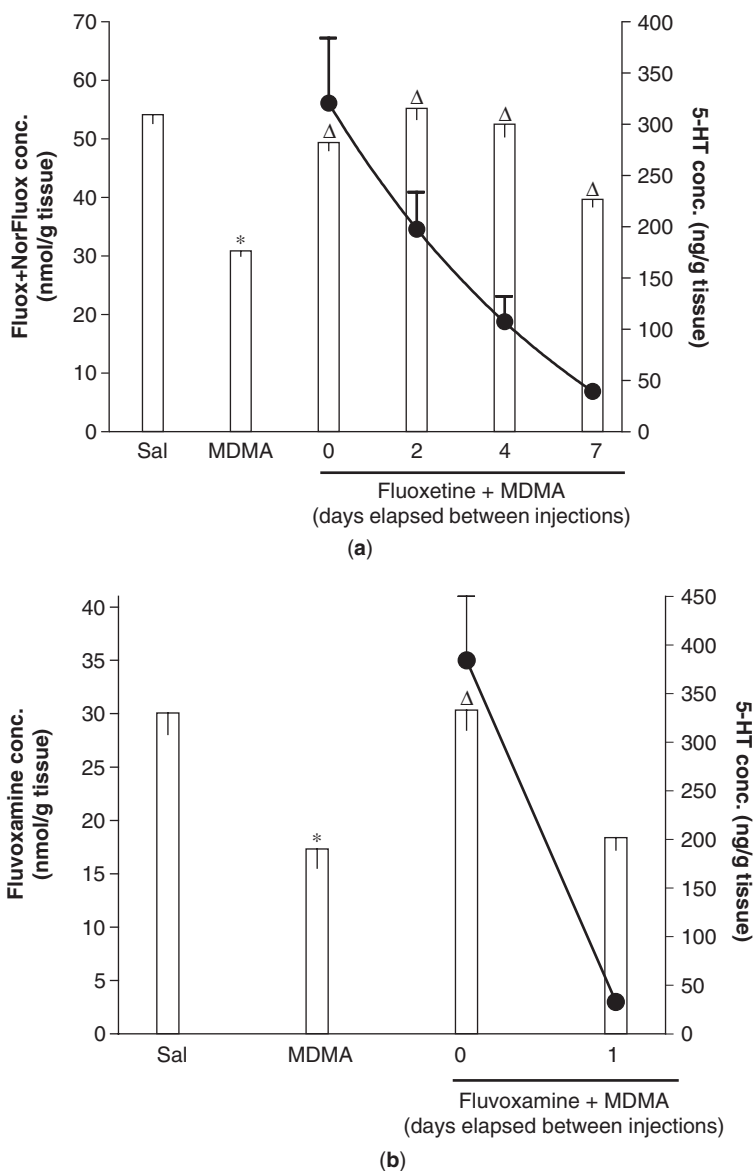

Figure 17.2 Effect of (a) fluoxetine and (b) fluvoxamine on MDMA-induced decrease in cortical 5-HT concentration 1 week after injection. Two injections of fluoxetine (10 mg/kg, i.p.) with an interval of 60 min were given 2, 4, or 7 days before MDMA (15 mg/kg, i.p.). Two injections of fluvoxamine (15 mg/kg, i.p.) with an interval of 60 min were given 1 day before MDMA. A group of animals received fluoxetine or fluvoxamine 5 min before and 55 min after MDMA. Results are shown as mean \pm standard error of the mean (SEM) ($n = 6-16$). Different from saline: (*) $p < 0.001$. Different from MDMA: (Δ) $p < 0.001$. Curves show the corresponding time course of fluoxetine plus norfluoxetine (a) and fluvoxamine (b) concentrations in cortex after administration of two doses of fluoxetine (10 mg/kg, i.p.) or fluvoxamine (15 mg/kg, i.p.) with an interval of 60 min. Levels were measured at 0.5 h and 2, 4, and 7 days after the last dose of fluoxetine and at 0.5 h and 1 day after the last dose of fluvoxamine. Results are shown as mean \pm SEM ($n = 5$ at each time point).

presence of fluoxetine and its main active metabolite norfluoxetine in the brain (Fig. 17.2). Both compounds inhibit the 5-HT transporter and could be blocking the entry of a toxic metabolite of MDMA into 5-HT nerve terminal [82]. In contrast to fluoxetine, fluvoxamine generates several metabolites, none of which appears to be pharmacologically active. Moreover, the parent compound undergoes a rapid plasma clearance in such a way that fluvoxamine brain concentrations are practically undetectable 24 h after injection (Fig. 17.2).

It has been reported that fluoxetine not only prevents MDMA-induced neurotoxicity but also inhibits hydroxyl radical formation [141]. Fluoxetine administration 1 h prior to or 4 h following MDMA administration reduced the MDMA-induced formation of 2,3-DHBA and also attenuated the MDMA-induced depletion of 5-HT in the striatum. As fluoxetine does not modify the *in vitro* generation of 2,3-DHBA, authors indicate that a potential mechanism by which fluoxetine attenuates the MDMA-induced formation of hydroxyl radicals is by preventing the entry into the 5-HT terminal of reactive substances that are capable of generating free radicals.

Not only is the long-term depletion of 5-HT dependent on the activation of the 5-HT transporter but, since fluoxetine is able to attenuate the immediate 5-HT release induced by MDMA in both the striatum [27] and hippocampus [23], it appears that acute MDMA-induced 5-HT release also involves a carrier-mediated mechanism.

Monoaminergic transporters also appear to be involved in MDMA-induced neurotoxicity in mice. MDMA induces a long-lasting depletion of dopamine concentration in the striatal neurons of the mouse, and administration of the dopamine uptake inhibitor GBR 12909 provides substantial protection [150]. Using *in vivo* microdialysis it has been shown that N-[4-methoxy-3-(4-methyl-1-piperazinyl)phenyl]-2'-methyl-4'-(5-methyl-1,2,4-oxadiazol-3-yl) [1,1-biphenyl]-4-carboxamide hydrochloride monohydrate (GBR 12909) inhibited the MDMA-induced increase in free-radical formation in the striatum and enhanced the acute release of dopamine induced by MDMA [130]. Altogether these data suggest that, in mice, (1) dopamine release does not involve a transporter-mediated mechanism, (2) MDMA probably enters into the dopamine nerve terminal by passive diffusion, (3) free-radical formation is not associated with dopamine release, and (4) free-radical-producing neurotoxic metabolites may enter the dopamine nerve ending via the dopamine uptake site.

17.1.4.3.5 Cytokines and Microglia. It is well established that cytokines such as interleukin-1 β , interleukin-6, and tumor necrosis factor- α increase body temperature by acting through direct or indirect mechanisms on the brain. In particular, interleukin-1 β has been shown to be involved in the development of the hyperthermic response induced by exogenous pyrogens such as lipopolysaccharide [151], turpentine [152], and leptin [153]. Administration of interleukin-1 β antibodies or an interleukin-1 receptor antagonist to experimental animals inhibits the rise in temperature induced by these external inflammatory stimuli.

Recently, it has been shown that immediately following MDMA administration to rats there is an acute and dramatic increase in interleukin-1 β concentration in the hypothalamus that appears at an early time point after MDMA administration and is of short duration, levels returning to basal values 12 h after drug injection [154]. A similar but less pronounced effect was observed in cortex. It is worth mentioning that under physiological conditions the hypothalamus produces significantly greater amounts of pro-interleukin-1 β than frontal cortex and that this precursor is

converted to its bioactive form and released in a more efficient way in the hypothalamus than in frontal cortex. Thus, pro-interleukin-1 β immunoreactivity, caspase-1-like protease activity, and interleukin-1 β levels are higher in the hypothalamus than in the frontal cortex [154, 155].

Interestingly, there was a clear dissociation in the time course of the changes induced by MDMA on body temperature and interleukin-1 β release. While a marked hyperthermia was evident within the first 20 min of MDMA administration [44], with rectal temperature peaking 60 min after treatment and remaining elevated for over 12 h, the increase in levels of interleukin-1 β peaked at 3 h [154]. These data, and the more definitive observation that intracerebroventricular administration of interleukin-1 receptor antibody did not modify the peak hyperthermic response immediately following MDMA, indicate that interleukin-1 β production could be a consequence, rather than the cause, of hyperthermia and that hyperthermia could represent a signal generated by MDMA which occurs early enough to allow secretion of interleukin-1 β and probably a host of other soluble factors from the microglia. In line with these results, when animals are kept at an ambient temperature of 4°C during MDMA treatment, the hyperthermic response is totally abolished and there is a significant reduction in interleukin-1 β production. These data all indicate that release of interleukin-1 β is, in part, a consequence of the hyperthermia [154].

The rise in interleukin-1 β release following MDMA is accompanied by an enhancement of pro-interleukin-1 β production and/or an increase in caspase-1-like protease activity, the enzyme required for maturation of interleukin-1 β , in the frontal cortex but not in the hypothalamus [155]. Interleukin-1 β is generated as an inactive 31-kDa precursor protein (pro-interleukin-1 β) [156] which is proteolytically processed into the 17-kDa mature interleukin-1 β by a specific intracellular cysteine protease, the interleukin-1 β converting enzyme (ICE), also termed caspase-1 [156]. MDMA increased the immunoreactivity of pro-interleukin-1 β in frontal cortex, not in hypothalamus, 3 and 6 h after administration. Caspase-1-like protease activity was increased in frontal cortex 3 h after MDMA injection compared with saline-treated animals. No change in caspase-1-like protease activity was observed in hypothalamus. Altogether these data indicate that MDMA alters, in a region-specific manner, the mechanisms which regulate interleukin-1 β production in the brain of Dark Agouti rats and suggest that the release of interleukin-1 β in hypothalamus may be regulated independently of caspase-1 activation.

In addition to increasing interleukin-1 β release, MDMA also induced an increase in the density of peripheral benzodiazepine receptor binding sites, labeled with [3 H]PK 11195 [(1-(2-chlorophenyl)-*N*-methyl-*N*-(1-methylpropyl)3-isoquinolinecarboxamide)], in both the hypothalamus and cortex of the rat. This increase could be reflecting an activation of microglia as revealed by immunohistochemical studies in the anterior hypothalamus. However, and in contrast to the increase in interleukin-1 β release, neither the upregulation of peripheral benzodiazepine receptor binding sites nor the staining for OX-42 (monoclonal antibody directed toward complement receptor 3), which stains activated microglia, was significantly modified when the hyperthermic response to MDMA was abolished. These results, together with the fact that the maximal microglial activation occurs 24 h after MDMA (when the hyperthermia induced by MDMA has disappeared), indicate that a hyperthermic response may not be necessary for the morphological changes that occur in the microglia.

17.1.4.4 *Functional Consequences of Neurotoxic Lesion.*

17.1.4.4.1 *On Thermoregulation.* While an MDMA-induced neurotoxic lesion does not alter the hyperthermic temperature response of rats to a further challenge dose of MDMA when the animals are housed in normal room temperature conditions (20°C), it does modify the response in rats housed in a warm (30°C) room. In such conditions, the hyperthermic response is prolonged compared to nonlesioned animals [50]. This prolongation appears to be due to the MDMA-induced loss of cerebral 5-HT since a prolonged response is also seen in rats pretreated with the 5-HT synthesis inhibitor *p*-chlorophenylalanine (PCPA) or either of the 5-HT antagonists methysergide and WAY 100635 [157]. The data suggest that a decrease in 5-HT function impairs heat loss in rats housed in warm conditions and is supported by the fact that PCPA pretreatment increases heat-induced mortality in rats housed at high ambient temperature [158, 159].

Other evidence indicates an MDMA-induced neurotoxic lesion can impair heat loss. When lesioned rats are placed in a warm environment and then returned to normal temperature conditions, their rectal temperature remains elevated for longer than control rats [49, 160]. Again normal heat loss mechanisms appear to have been impaired by the neurotoxic lesion. The experiment with WAY 100635 indicates the involvement of the 5-HT_{1A} receptor and it can be proposed that the lesion impairs 5-HT release onto 5-HT_{1A} receptors, thereby producing this defect in thermoregulation. No clinical studies have been performed, but the results suggest that heavy users of MDMA should exercise caution in using the drug in hot room conditions in order to avoid possible problems with hyperthermia.

17.1.4.4.2 *On Behavior.* Most experimental studies on MDMA have mainly focused on the behavioral changes associated with the immediate neurochemical effects induced by MDMA. There is relatively little information on the consequences of the long-lasting depletion of brain 5-HT induced by MDMA on behavioral and cognitive functions.

Marston and coinvestigators [161] performed a study to explore the posttreatment consequences of a 3-day neurotoxic exposure to MDMA in the rat using a variety of behavioral paradigms. Male Lister Hooded rats were injected twice daily with ascending doses of MDMA (10, 15, and 20 mg/kg) over 3 days and behavior was analyzed over the following 16 days. Three weeks after the period of exposure to MDMA, rats showed a persistent depletion of 5-HT (40–60%) in cortex, hippocampus, and striatum and no change in dopamine levels. MDMA exposure resulted in a lasting cognitive impairment as it was found that the MDMA-treated group did not show the progressive improvement in performance of the delayed nonmatched-to-place procedure seen in the control group. Delay-dependent impairments in accuracy are often attributed to perturbations in short-term memory and related systems. The level of locomotor activity of the MDMA-treated rats was significantly greater than the saline controls during the MDMA dosing period and 3 days later but thereafter was indistinguishable from control values. Different results have been reported by Wallace and coinvestigators [162] following administration of 10 mg/kg of MDMA four times 2 h apart to Sprague–Dawley rats and subsequent testing of diurnal and nocturnal spontaneous locomotor activity. Two weeks after dosing rats showed a depletion of striatal 5-HT content of approximately 50% and also exhibited significant reductions in both diurnal and nocturnal locomotor

activity. This effect may be due to the reported regulatory actions of 5-HT on the sleep–wake cycle [163, 164]. In fact, rats with a significant reduction in the neocortical density of 5-HT transporter 3 weeks after exposure to a single 15-mg/kg dose of MDMA show long-term changes in regulation of circadian rhythms and sleep generation [165].

Prior MDMA exposure also alters anxiety-related behaviors, but results have been conflicting and may be dependent on the basal anxiety level of the rat strain being investigated [166]. Using the same paradigm for behavioral testing (elevated-plus maze), obtaining a similar decrease in cerebral 5-HT concentration (30–40% loss), and considering a similar delay for testing animals following MDMA administration (70–90 days posttreatment), Morley and coinvestigators [167] reported anxiety-like behaviors in Wistar rats while Mehan and coinvestigators [168] described an apparent anxiolytic response in Dark Agouti rats. It thus appears that a 5-HT lesion may produce an anxiolytic response in an anxious strain (Dark Agouti) but an anxiogenic response in strains displaying low endogenous anxiety (Wistar rats) [166].

Acute exposure of young Lister Hooded rats to MDMA produces a long-term anxiety-like behavioral response in the social interaction paradigm, even though there were only modest reductions in indole brain concentrations and no change in the density of cortical 5-HT transporters [167]. Similar results were obtained following exposure of young Wistar rats to low and repeated doses of MDMA, the anxiety-related behavior being accompanied by changes in 5-HT_{2A} receptor function [169].

Recently McGregor's team [170] has performed a study to investigate the long-lasting behavioral and neurochemical effects of combined MDMA and methamphetamine administration in the rat. Animals received four injections, one every 2 h, of MDMA (2.5 or 5 mg/kg per injection) or methamphetamine (2.5 or 5 mg/kg per injection) given alone or in combined low doses (1.25 + 1.25 mg/kg per injection or 2 + 2 mg/kg per injection). Several weeks after drug administration, both MDMA + methamphetamine groups, both metamphetamine groups, and the higher dose MDMA group showed decreased social interaction relative to controls while both MDMA + methamphetamine groups and the lower dose MDMA group showed increased anxiety-like behavior on the emergence test. MDMA treatment caused 5-HT and 5-HIAA depletion in several brain regions, while methamphetamine treatment reduced dopamine in the prefrontal cortex. Combined MDMA + methamphetamine treatment caused 5-HT and 5-HIAA depletion in several brain regions and a unique depletion of dopamine and DOPAC in the striatum. These data have potentially important implications for public awareness as they demonstrate specific adverse behavioral and neurochemical effects of MDMA and methamphetamine given alone at relatively low doses in a novel one-day regimen. Results also show that coadministration of MDMA and methamphetamine leads to adverse effects that may be more pronounced and consistent than those observed with similar doses of MDMA or methamphetamine administered alone.

As mentioned above, the study of Marston and coinvestigators [161] was the first to report that administration of ascending doses of MDMA for three days resulted in an impaired cognitive behavior and a pronounced depletion of 5-HT brain concentration. Subsequently, Broening and coinvestigators [171] reported that exposure to MDMA in rats during stages analogous to early and late third-trimester human fetal brain development induces specific types of long-term learning and memory impairments. MDMA exposure on post natal days P11–P20 resulted in dose-related

impairments of sequential learning and spatial learning and memory. These learning deficits reflect a developmentally specific vulnerability in that they were selective, affecting only those animals treated on P11–P20 and not those treated on P1–P10. The effects were also long term in that they were seen in the offspring as adults and not related to any long-term changes in 5-HT, dopamine, or noradrenaline.

An impairment of nonspatial working memory has also been reported in rats exposed to intermittent administration of MDMA every fifth day from P35 to P60 trying to model the typical intermittent MDMA human use pattern in adolescent Sprague–Dawley rats. Five days after dosing animals showed a significant reduction of about 25% in the density of 5-HT transporters in cerebral cortex, not in hippocampus [172].

In nonhuman primates there have been few studies performed to evaluate cognitive functions such as learning and memory. Frederick and coinvestigators [173–175] did not find any long-term alteration in performance on a number of operant tasks in rhesus monkeys exposed to neurotoxic doses of MDMA. Thus, repeated exposure to doses of MDMA sufficient to produce long-lasting changes in brain neurotransmitter systems results in residual effects (e.g., tolerance, sensitivity) on behavioral task performance when subjects are subsequently challenged with acute MDMA, whereas baseline (nonchallenged) performance of these tasks after such exposure generally remains unchanged. Similarly, Taffe and coinvestigators [176] found no apparent lasting effect induced by MDMA on a battery of cognitive/behavioral measures in rhesus monkeys with cerebrospinal fluid (CSF) 5-HIAA concentration reduced by 40–50%. Winsauer and coinvestigators [177] showed that neurotoxic doses of MDMA failed to disrupt learning in squirrel monkeys in spite of impairment being demonstrated following administration of fenfluramine. Nevertheless, although cognitive/behavioral measures performed in nonhuman primates following neurotoxic doses of MDMA are normal, brain stem auditory-evoked potentials are abnormal for a period of at least three months after MDMA dosing [176]. This long-lasting effect is consistent with a loss of 5-HT innervation of brain stem auditory nuclei and suggests that auditory pathways are much more sensitive to the deleterious effect of MDMA. It is interesting to note that studies which have failed to show memory impairment in human beings employed nonauditory tasks [178] while those reporting memory disruption showed some auditory memory task [179, 180].

17.1.5 Biochemical and Functional Changes in Human Brain

Neuroimaging studies performed on recreational users of MDMA have shown sustained reductions in brain 5-HT transporter density [181–183] which positively correlated with the extent of previous MDMA use [183] and duration of abstinence [182]. The effect might be more pronounced in women and reversible after prolonged abstinence [184, 185]. A reduction in the CSF 5-HIAA concentration has also been observed in recreational users of MDMA, the reduction being greater in females (46%) than in males (20%) [186, 187]. MDMA users show a downregulation of 5-HT_{2A} receptors in the cerebral cortex while in the abstinent MDMA user group there is an upregulation of 5-HT_{2A} receptors. The combined results of this study suggest a compensatory upregulation of postsynaptic 5-HT_{2A} receptors in the occipital cortex of ex-MDMA users due to low synaptic 5-HT levels [188]. MDMA users do not appear to suffer any reduction in nigrostriatal dopamine

neurons. However, subjects regularly using amphetamine in addition to MDMA did display a 20% loss in the density of striatal dopamine transporters [189].

Neuroendocrine tests have shown that abstinent MDMA users exhibit blunted cortisol and prolactin responses to fenfluramine challenge compared to controls, the prolactin response still being observed after one year of abstinence [190]. The presence of a long-lasting impairment of brain serotonergic function in recreational users of MDMA could potentially account for the reported cognitive and mood impairments, particularly when there is a relationship between the extent of lifetime consumption of MDMA and the severity of cognitive deficits [191–193].

Long-term MDMA use impairs performance in a multitude of cognitive abilities (most notably memory, learning, attention, executive function). Deficits in verbal and visual memory have been most frequently observed [180, 185, 193–195]. Users also show impaired verbal learning, are more easily distracted, and are less efficient at focusing attention on complex tasks [196–198].

Cognitive impairments have also been detected in a recent pilot study focused on adolescent MDMA users [199]. It appears that many of the neuropsychological performance problems reported to occur in MDMA users are not reversed by prolonged abstinence, suggesting the existence of a selective neurotoxic lesion [200]. It is essential to mention that many subjects are polydrug users; therefore, it cannot be stated unequivocally that any effect seen results solely from MDMA use. Cannabis users, whether or not they also used MDMA, showed significantly impaired memory function on word free recall and on immediate and delayed story recall compared to nonusers. The findings highlight the importance of controlling other drug use (particularly cannabis) when investigating persistent effects of MDMA in humans [201]. Gouzoulis-Mayfrank and coinvestigators [202] performed a comprehensive cognitive test battery on 28 recreational Ecstasy users with concomitant use of cannabis only and two equal-size matched groups of cannabis users and nonusers. The test battery included tests of attention, memory and learning, frontal lobe function, and general intelligence. Ecstasy users performed worse than one or both control groups in the more complex tests of attention, in memory and learning tasks, and in the tasks reflecting aspects of general intelligence. Poorer performance scores or longer reaction times in the working memory, verbal memory, and divided attention tasks were associated with heavier Ecstasy and heavier cannabis use. These results raise the concern that Ecstasy use, even in typical moderate recreational doses and possibly in conjunction with cannabis use, may lead to a subclinical cognitive decline in otherwise healthy young people.

Alternatively the problem may relate to the combination of MDMA with another recreational compound; a significant percentage of Ecstasy tablets contain psychoactive compounds other than MDMA. Therefore, although only MDMA and other amphetamine derivatives have been clearly demonstrated to produce neurotoxicity, the possibility cannot be ruled out that neurotoxicity is due to a combination of MDMA and other compounds ingested.

17.2 GHB

In recent years, γ -hydroxybutyric acid (GHB) has grown in popularity as a drug of abuse, due mainly to its ability to produce euphoria and promote relaxation,

increase sociability, and produce a heightened sense of sexuality and an increased disinhibition similar to that produced by ethanol [203]. The drug is most commonly referred to on the street as “liquid Ecstasy” but also goes under the names “liquid X,” “liquid E,” “Grievous Bodily Harm” (a play-on-words with the initials), and “Salty Water” due to the slightly salty taste of its preparations. GHB is usually found as a clear, colorless liquid, almost tasteless with a slight salty taste which is easily masked in alcoholic drinks. These characteristics together with its amnesic and hypotonic effects have led to its use in some cases of “date rape.”

The drug was first synthesized in 1960 [204] as an orally active analog of the neurotransmitter γ -aminobutyric acid (GABA), with the capacity to cross the blood–brain barrier [205]. Due to its ability to induce sleep and coma, its potential use as an anesthetic was explored, but its lack of sufficient analgesia and high incidence of vomiting as well as ability to cause convulsions limited its use.

The drug was first introduced into the North American market in the early 1990s as a dietary supplement available in health food shops for the treatment of anxiety and insomnia and to increase body mass in athletes and body builders. There have been reports of the therapeutic potential of GHB in the treatment of alcohol and opioid withdrawal, but such studies are far from conclusive [206–208].

Reports of its adverse effects followed soon after the introduction of GHB into the market [209], and this led to its prohibition, by the Food and Drug Administration (FDA), for use in humans except under medical prescription. In March 2000, the FDA reclassified GHB as a Schedule I controlled substance. In 2002, the FDA approved the use of GHB in patients suffering from narcolepsy with cataplexy. For this condition only, Xyrem was included in Schedule III of the Controlled Substances Act for medicinal use. Meanwhile the illegal use of GHB remains under the control of Schedule I [210].

GHB is a short-chain fatty acid found in mammalian brain [211] and was first identified in human brain in 1963 [212]. GHB is synthesized during the metabolism of the neurotransmitter GABA via an intermediate product, succinic semialdehyde, by means of the enzyme succinic semialdehyde reductase [213]. However, controversy exists as to whether GABA is the principal endogenous source of GHB. A marked reduction in GABA levels in the brain due to the administration of a glutamate decarboxylase inhibitor does not modify GHB levels [214]. In addition, GHB is found in peripheral tissues such as heart, kidney, and muscle at a higher concentration than that of GABA, suggesting an extraneuronal origin [215, 216]. It has been suggested that another compound in the brain, 1,4-butanediol, could also give rise to GHB by the action of alcohol dehydrogenase and aldehyde dehydrogenase [214, 217].

GHB is rapidly absorbed by oral administration [218], and its effects are evident after 15 min with peak plasma levels being reached between 30 and 60 min after consumption, depending on the dose [205, 219]. It does not bind significantly to plasma proteins [219]. Within the therapeutic range, GHB follows nonlinear pharmacokinetics. At low doses of 12.5 mg/kg the half-life is estimated at 20 min whereas higher doses exhibit longer half-lives. It is mainly eliminated by metabolism to carbon dioxide with only 2–5% being eliminated in urine [220].

17.2.1 Pharmacological Effects

GHB exhibits a steep dose–response curve leading to the appearance of adverse effects with a small increase in dose. The principal effects are those relating to the

central nervous system (CNS) and cardiovascular and respiratory systems; GHB does not appear to affect the hepatic or renal systems [220]. For the most part, the adverse effects are acute in nature, appearing in the first 15 min and disappearing after 7 h.

Adverse effects on the CNS constitute the majority of GHB acute toxic reaction reports. They appear even at intermediate doses (25–50 mg/kg) and consist of sleepiness, dizziness, vertigo, and headaches [218, 219]. At higher doses it can cause the rapid onset of a state of coma (with no participation of the reticular activating system) which is short-lived and apparently fully reversible [221].

With regard to the cardiovascular system, GHB produces bradycardia both as an anesthesia inducer as well as in overdose with cardiac rhythms of fewer than 55 beats per minute having been recorded. Hypotension often accompanies the reduced heart rate.

Respiratory depression, difficulty breathing, and apnea have all been reported following GHB consumption [209, 220].

All the effects listed above are enhanced by ethanol such that the ingestion of both drugs together produces greater toxic effects than those produced by each drug taken alone [222]. In fact, 64% of the emergency room visits due to GHB involve the use of ethanol as well [223].

GHB also produces effects on the visual system, such as myopia and pupils unreactive to light, and the gastrointestinal system, such as nausea and vomiting, as well as motor effects such as clonic movements and uncontrollable shaking and slight hypothermia [209, 220, 224].

On occasion GHB has been associated with psychopathological symptoms such as hostile behavior, belligerence, and agitation. Other psychiatric symptoms such as delirium, paranoia, depression, and hallucinations have also been described [225].

Studies in humans, reports from emergency room admittances, as well as surveys and statements, all point toward a withdrawal syndrome of the characteristics produced by ethanol or benzodiazepine withdrawal. The syndrome appears 1–6 h after the last dose [226] and can last up to 15 days. Initial symptoms include insomnia, anxiety, agitation, tremors, nausea, and vomiting. This is followed by autonomic nervous system instability which manifests itself with diaphoresis, hypertension, shaking, and tachycardia. Following withdrawal after chronic or high-dose use, psychotic symptoms, hallucinations, and delirium have been described [227]. A prolonged abstinence syndrome period has been described which lasts between three and six months and is characterized by dysphoria, anxiety, memory problems, and insomnia. During this time the risk of relapse or development of ethanol or benzodiazepine dependence is high [228].

17.2.2 Mechanism of Action

The mechanism of action of GHB has not been completely elucidated. Although it was first synthesized as a GABA analog, early experimental evidence showed it to have different biochemical and behavioral effects.

There is a large body of evidence indicating that GHB produces many of its effects by means of interaction with the GABAergic system. GHB has no affinity for the GABA_A receptor [229] but acts as a partial agonist at the GABA_B receptor [230], although at concentrations higher than those normally found in the brain. In

GABA_B (–/–) knockout mice, GHB does not produce hyperlocomotion, hypothermia, increases in dopamine synthesis, or increases in delta waves as measured by EEG, effects which are observed in wild-type mice [231]. Therefore, it appears that at least some of the effects produced by GHB are mediated by the GABA_B receptor.

However, GHB does not consistently exhibit a GABA agonist profile, suggesting that it must act, at least in part, through some other mechanism. This naturally occurring compound has been proposed as a neurotransmitter or neuromodulator in its own right. GHB is found in high concentrations in the substantia nigra and hypothalamus [215, 232]. It is released from neurons in a calcium-dependent manner in response to potassium, and these neurons contain highly specific sodium-dependent uptake sites [233, 234]. In addition, G-protein-coupled GHB receptors have been located in dopaminergic areas on GABAergic and/or enkephalinergic neurons [235].

Regardless of the exact mechanism of action, exogenous administration of GHB has been shown to modulate various neurotransmitter systems, including the dopaminergic system. GHB inhibits the release of dopamine [236], and animals show sedation and a dose-dependent reduction in locomotor activity [231, 237]. The reduction in dopamine is inhibited by GABA_B antagonists [238]. At high doses the rapid reduction in dopamine release is followed by an accumulation of tissue dopamine in the frontal cortex [239], most likely due to an increase in the activity of tyrosine hydroxylase, and an increase in its release in the striatum and various areas of the corticolimbic system [240].

GHB does not bind to opioid receptors [241], although some of its effects can be reproduced by opioid agonists. Local administration of GHB produces an increase in the release of endogenous opioids which appears to be mediated by the decrease in dopaminergic function [241].

GHB increases 5-HT turnover [242] and synthesis through a modulatory effect on GABA release [213].

17.2.3 GHB and Addiction

In drug discrimination studies in rats, GHB has been shown to be partially substituted for by morphine, lysergic acid diethylamide (LSD), *d*-amphetamine, GABA agonists (baclofen), and chlordiazepoxide [243]. These effects appear to be mediated, in part, by the GABA system since 3-Aminopropyl (diethoxymethyl) phosphinic acid (CGP35348), a GABA_B receptor antagonist, blocked discrimination both at low and especially at high doses of GHB [244]. In addition, GHB has been shown to substitute for intermediate doses of ethanol [245].

In reinforcement studies, after repeated GHB administration, animals showed a place preference suggesting that the reinforcing effects of the drug are weaker than those produced by cocaine or opiates, which require only single exposure [246].

Self-administration studies indicate that rats trained to drink GHB prefer GHB in a subsequent two-drinking-bottle paradigm [247]. Furthermore, rats receiving GHB in response to nose-pokes will respond with more nose-pokes than those animals who are yoked to passively receive the same dose of GHB and who receive a vehicle in response to nose-pokes [248].

There is some evidence of tolerance to the motor dysfunction effects in mice and there is cross-tolerance with ethanol [249]. A withdrawal syndrome has been

described using the same scale as is used to evaluate ethanol intoxication withdrawal following repeated daily administration for three to six days [250].

17.3 KETAMINE

Another popular club drug is ketamine, a phencyclidine derivative, first introduced into clinical practice in the 1960s as a dissociative anesthetic [251]. Its clinical use has diminished, but it is still used in circumstances where its dissociative/analgesic effects are advantageous, such as in patients with burns. It is administered by the intravenous or intramuscular routes, and drugs such as diazepam are often coadministered in order to reduce the incidence of hallucinations and/or psychosis symptoms. These symptoms appear to be less common in children. Ketamine is still quite widely used in veterinary practice for the sedation of animals for surgery, transport, or euthanasia [252].

It is thought that ketamine first entered the club scene as an adulterant of MDMA (Ecstasy), but it is now consumed in its own right [253]. On the street it is known by a number of names, including “K,” “Special K,” “Vitamin K,” or “Kit-kat.” Supply of ketamine originates mainly from the diversion of prescription products. The drug can be injected either intravenously or intramuscularly [254], taken orally either as a powder or liquid, snorted as a powder, or smoked [255]. Orally it is less well absorbed and undergoes extensive first-pass metabolism [254]. The drug is tasteless, odorless, and colorless, which makes it suitable for its secret addition to drinks in order to facilitate sexual assault. This property, as well as its ability to cause anterograde amnesia and hallucinations making the victims unreliable as witnesses, has led to its use in cases of date rape [256].

17.3.1 Pharmacological Effects

Ketamine has a rapid onset of action, lasting approximately 30–45 min. Low doses produce a dreamlike dissociative effect with analgesia and can lead to involuntary lesions. Higher doses can lead to hallucinations and vivid dreams as well as to amnesia. Users describe an “out-of-body” experience where the mind is taken to “K-land” or “K-hole,” an experience that can be either spiritual or unpleasant depending on the individual [257]. Neurological toxicity may manifest itself as nystagmus, mydriasis, agitation, slurred speech, confusion, delirium, floating sensation, hypertonus, rigidity, anxiety, vivid dreams, hallucinations, hostility, and seizures [255]. Cardiovascular toxicity includes hypertension, tachycardia, and palpitations, and respiratory toxicity may appear in the form of depression and apnea [252]. Rhabdomyolysis has also been reported [258]. Its effects can be potentiated by ethanol, GHB, or benzodiazepine ingestion.

Ketamine is an *N*-methyl-D-aspartate (NMDA) agonist that also acts at non-NMDA–glutamate receptors, nicotinic and muscarinic cholinergic receptors, σ receptors, monoaminergic receptors, opioid receptors, and sodium and calcium channels. At the NMDA channels, ketamine binds noncompetitively to the phencyclidine site and inhibits glutamate activation of the channel. The drug also stimulates nitric oxide synthesis and acts as an inhibitor of norepinephrine, dopamine, and 5-HT uptake [251, 259, 260]. In addition, it produces dopamine release in the nucleus accumbens [261],

and there are reports of the induction of dependence in rats [262]. Therefore, it appears that ketamine has the potential to be an addictive drug of abuse.

17.4 FLUNITRAZEPAM (ROHYPNOL)

Flunitrazepam is a fast-acting potent hypnotic/sedative benzodiazepine which, although never approved for use in the United States, has been widely used in Europe and some Latin American countries under the brand name Rohypnol for the treatment of insomnia, sedation, and preanesthesia [252]. The drug has become increasingly popular among teenagers and young adults and is often consumed in combination with alcohol and/or other illicit drugs. Reports suggest that it is the preferred benzodiazepine of heroin addicts and has also been identified in numerous cases of drug-facilitated sexual assault due to its induction of anterograde amnesia.

The drug is generally taken orally as the commercially available pill or dissolved in a drink. The drug has good bioavailability, is rapidly distributed from plasma into tissue, and is metabolized by the liver into two active compounds [263]. The effects appear after approximately 20–30 min and last 4–6 h, although residual effects can be observed at much later time points. The half-life of the drug is approximately 20 h and the metabolites are excreted renally.

17.4.1 Pharmacological Effects

As with other benzodiazepines, flunitrazepam produces a reduction in anxiety, muscle relaxation, and sedation. In addition, the drug produces amnesia which is enhanced by the concurrent ingestion of alcohol.

At higher doses, flunitrazepam can cause lack of muscle control and loss of consciousness. The drug can produce hypotension, dizziness, confusion, visual disturbances, urinary retention, and, occasionally, aggression [263].

As with other benzodiazepines, flunitrazepam can cause dependence and a withdrawal syndrome, although due to its long half-life this may take several days to appear and persists for weeks after the last dose. The symptoms include headache, tension, anxiety, restlessness, insomnia, loss of appetite, tremor, and perceptual disturbances.

17.5 LSD

LSD belongs to the hallucinogenic class of drugs. Hallucinogens are defined as pharmacologically active substances which alter consciousness, often in a dramatic and unpredictable manner, and which at high doses can produce delirium, hallucinations, separation from reality, and in some cases death, which is not due to overdose. These substances are also referred to as psychomimetics since they alter cognitive functions and personality and mimic psychosis.

The hallucinogens are included in Schedule I of the Controlled Substances Act and are traditionally classified into one of two groups: phenylalkylamines (mescaline, DOB, DOI) and the indolealkylamines (DMT, 5-MeO-DMT, psilocybin, LSD, harmaline, bufotenine) (Table 17.1).

TABLE 17.1 Hallucinogens: Dose, Duration of Effects, and Route of Administration in Humans

Hallucinogen	Dose (mg)	Duration of Effects	Route of Administration
DMT	60–100	1 h	Smoked, inhaled, nasal, injection
5-MeO-DMT	6–20	20–30 min	Smoked, inhaled, nasal, injection
Psilocybin	6–20	4–6 h	Oral
LSD	0.06–20	10–12 h	Oral
Mescaline	200–400	10–12 h	Oral
DOB	1–3		Oral
DOI	1.5–3		

DMT: *N,N*-dimethyltryptamine; 5-MeO-DMT: 5-methoxy-dimethyltryptamine; DOB: 2,5-dimethoxy-4-bromoamphetamine; DOI: 2,5-dimethoxy-4-iodoamphetamine

LSD is a prototypical hallucinogen which was first introduced to Europe and North America in 1949 [264]. It is a semisynthetic molecule derived from lysergic acid, which is produced by a fungus which grows on rye. Its effects were first identified by a chemist, A. Hoffman, working for Sandoz Pharmaceuticals, who experienced the mental effects of the drug after working with the compound [265]. The drug, as with most hallucinogens, is orally active and is the most potent of all hallucinogens [266]. At the other end of the spectrum is mescaline, which is the least potent of the classical hallucinogens (Table 17.1).

17.5.1 Pharmacological Effects

The main effects of LSD, which are common to most of the hallucinogens, are listed in Table 17.2. It is generally considered safe from a physiological standpoint since it alters consciousness at low doses which are not toxic to the cardiovascular, renal, or hepatic systems. At lower doses (25–50 µg) the drug produces mild visual effects which are not considered hallucinations or distortions of perception. At higher doses (250 µg) the drug produces sympathetic arousal characterized by increased pulse and blood pressure, dilated pupils causing blurred vision, hyperreflexia, and slight pyrexia [264]. In one reported case of multiple overdose, hemorrhage occurred which may have been mediated by LSD antagonism of platelet 5-HT function [267].

17.5.2 Mechanism of Action

LSD appears to mediate most its hallucinogenic effects by its action at the 5-HT_{2A} receptor. Studies carried out in experimental animals reveal that 5-HT_{2A} receptor antagonists such as ketanserin and pirenperone block the discriminative effects of both classes of hallucinogens in rats trained to discriminate between the effects of saline and the training drug [268, 269]. In addition, other studies with more highly selective antagonists of the 2A receptor over the 2C receptor have confirmed the 5-HT_{2A} receptor as the target [270]. Similar observations have been made in humans

TABLE 17.2 Pharmacological Effects and Adverse Reactions of Hallucinogens

Somatic Alterations	Alterations of Perception	Mental Alterations	Adverse Reactions
Dizziness, weakness, shaking, nausea, sleepiness, paresthesias, blurred vision	Distortion of shapes and colors, difficulty in focusing, heightened sense of hearing, synesthesias (unusual)	Mood changes (happiness, sadness, or irritability), tension, distorted perception of the passage of time, difficulty in expressing thoughts, depersonalization, dream-like state, and visual hallucinations	Anxiety, agitation (bad trips), flashbacks, precipitation of psychosis and depression (in susceptible individuals), suicide

[271, 272]. The development of tolerance, as seen in both animals and humans, appears to be related to the selective downregulation of the 5-HT_{2A} receptor following daily administration [273].

Hallucinogen-induced activation of 5-HT_{2A} receptors located on neocortical pyramidal neurons leads to an increase in glutamate levels in the prefrontal cortex [274] presumably through an action mediated by the presynaptic receptors of thalamic afferents. This release of glutamate is thought to contribute to the behavioral effects produced by the hallucinogens since antagonism of the metabotropic glutamate mGlu2/3 receptor, a putative presynaptic autoreceptor on glutamatergic neurons [275], increases appropriate responding in rats trained to discriminate LSD [276]. Opposite effects were observed with an mGlu2/3 agonist. Agonists and antagonists of the mGlu2/3 receptor have been observed to decrease and increase glutamate release, respectively [277, 278].

Although activation of 5-HT_{2A} receptors is accepted to be an essential component for the acute behavioral effects of the hallucinogens, it is possible that interaction with other receptors in the CNS may modulate their overall psychopharmacological effect. The hallucinogens, with the exception of LSD, have no affinity for dopaminergic receptors or for the dopamine transporter and therefore do not directly alter dopaminergic neurotransmission. However, systemic administration of DOI produces a 5-HT_{2A}-mediated increase in dopamine release in the prefrontal cortex [279], and local infusion of DOI in the nucleus accumbens also increases dopamine release [280]. Therefore it is possible that dopamine may participate in some of the behavioral effects of these drugs. In fact, it is thought that later onset behavioral effects of LSD appear to be mediated by dopamine pathways [281].

17.5.3 Hallucinogens and Addiction

In contrast to other drugs of abuse, the hallucinogens do not produce dependence or addiction and are not considered to be reinforcing substances [282] in spite of producing alterations in dopamine neurotransmission either directly or indirectly

(see above). In fact, in the rhesus monkey LSD produces negative reinforcement [283], although in the rat the drug appears to have weak reinforcing properties [284] which may be related to the drug's direct action on dopamine receptors. This lack of addictive properties is interesting to note in light of the fact that modifications of dopamine neurotransmission, in particular dopamine release in the mesolimbic pathways, seem to be involved in the mechanism of action of drugs of abuse which cause dependence.

Studies designed to train animals to self-administer classical hallucinogens have failed, indicating that these substances do not possess the pharmacological properties necessary to establish and maintain a state of dependency. The drugs are generally consumed sporadically in a noncompulsive manner, and the majority of experimental first-time consumers do not go on to establishing a pattern of regular consumption. This pattern of consumption contrasts with the compulsive nature of amphetamine, cocaine, and opiate abuse which alter the pathways of reward and produce craving.

Tolerance to the behavioral effects of LSD occurs after daily administration for four to seven days and lasts for approximately three days [285]. Cross-tolerance occurs between LSD and other hallucinogens such as psilocybin and mescaline [286, 287].

17.6 SUMMARY

This chapter summarizes the latest literature on MDMA (Ecstasy), the most popular drug used by teens and adults in raves and other dance parties, and other compounds also categorized as club drugs—GHB, ketamine, Rohypnol, and LSD. Consumption, in general, appears to have increased in Western countries over the last 20 years, although trends show a variety of users and settings. Each drug produces diverse characteristic acute behavioral and biochemical effects which require different specific acute-care protocols. However, all of them share the common property of producing rewarding effects probably by activation of the mesolimbic system and the release of dopamine in the nucleus accumbens. MDMA induces long-lasting neurochemical changes reflected by a loss of 5-HT nerve terminals in the brain of rats, guinea pigs, and nonhuman primates. An increasing number of neuroimaging studies indicate that damage might also appear in human beings. The fact that the doses of MDMA that produce damage in experimental animals are similar to that used by humans places consumers in an area of high risk even after relatively short-time exposures to Ecstasy.

18.1 INTRODUCTION

Comprised of the dried leaves of the cannabis plant, marijuana (*Cannabis sativa*) is the most commonly abused illicit substance in the United States today, particularly among adolescents. In 2004, nearly half of seniors in high school had tried marijuana at least once and 20% were current users [1]. Further, while the number of regular adult users was approximately the same during the early part of this decade, the prevalence of marijuana abuse and dependence among these users (especially among racial and ethnic minorities) significantly increased, suggesting a combination of causal factors [2]. Yet, marijuana use is not a new phenomenon. Marijuana and other

constituents of the cannabis plant (e.g., hashish) have a long history of medicinal and religious use which dates back to ancient China. Even in the United States, marijuana was commonly used for medicinal purposes (e.g., nausea, arthritis) and as an intoxicant until after World War I. In the 1930s, however, a concerted effort by the Federal Bureau of Narcotics (a predecessor of the Drug Enforcement Administration) resulted in a change in public attitude toward marijuana. It became to be perceived as a “gateway drug” that led to addiction to “harder drugs” such as heroin. This new perception culminated with the Controlled Substances Act of 1970, in which marijuana was listed as a Schedule I drug with high abuse potential and no accepted medical use. The current debate over medical marijuana highlights this dichotomy between the demonstrated abuse properties of marijuana (as codified by its classification as a Schedule I drug) and growing evidence of its therapeutic potential for a wide variety of medical problems.

Scientific interest in marijuana, although relatively recent, has increased in response to several important discoveries in the field. First, the primary psychoactive constituent of the marijuana plant, Δ^9 -tetrahydrocannabinol (Δ^9 -THC), was isolated and identified [3]. Identification of this substance (Fig. 18.1) allowed further clinical and preclinical research to characterize its pharmacological effects in the body and on behavior. It also allowed manipulation of dosage so that dose dependence of these effects could be evaluated as well as better determination of the psychoactive potency of marijuana. In recent years, the average Δ^9 -THC content of street marijuana in the United States has increased to greater than 4%, although exact concentration in any sample varies considerably depending upon the growing conditions, the plant variety, and the preparation. For example, sinsemilla, the dried flowering tops of unfertilized female plants, may have Δ^9 -THC concentrations as high as 20%. Although it is hypothesized that the effects of the numerous other unique chemical constituents of marijuana (cannabinoids) may modulate the primary effects of Δ^9 -THC, direct

Figure 18.1 Structures of Δ^9 -THC, anandamide, and 2-arachidonylglycerol.

evidence for their role in marijuana's pharmacological effects is lacking. Hence, most of the preclinical mechanistic research on the pharmacological effects of marijuana is actually research on the effects of Δ^9 -THC.

A second discovery that increased scientific interest in marijuana was identification of a cannabinoid receptor (CB₁) in the brain [4]. Prior to this discovery, it was theorized that Δ^9 -THC and other highly lipophilic cannabinoids produced their effects in the central nervous system by disordering neuronal cell membranes and hence interfering with their normal function. Despite the membrane perturbation theory, however, there was ample evidence for a specific action of cannabinoids. Δ^9 -THC is a highly potent drug that produces a distinct profile of pharmacological effects with a strict structure–activity relationship. Each of these factors suggests a selective receptor-mediated action rather than generalized disruption of membranes. In addition, synthetic cannabinoid derivatives were prepared that were extremely potent and enantioselective, thereby enhancing the likelihood of a receptor mechanism. Direct evidence for cannabinoid receptors, however, awaited development of a radiolabeled ligand with which to perform ligand binding studies.

Analysis of binding data with [³H]CP 55,940, the first radiolabeled ligand for CB₁ receptors, revealed a single site that possessed saturable and reversible binding and that displayed selectivity for cannabinoids [4]. Further, the affinity of cannabinoids for this binding site correlated well with their potency in a variety of pharmacological assays, including production of antinociception, catalepsy and hypothermia, and suppression of spontaneous locomotor activity in mice [5]. In addition, a high correlation was found between CB₁ binding affinity and *in vivo* potency in the rat drug discrimination model (an animal model of the subjective effects of psychoactive drugs) and for marijuana-like psychoactivity in humans [6]. Subsequently, a second cannabinoid receptor (CB₂) was discovered in the periphery. Both CB₁ and CB₂ receptors have been cloned [7, 8].

An interest in the endogenous ligand for these cannabinoid receptors sparked the discovery of arachidonoyl ethanolamide (anandamide) in porcine brain [9]. Later, a number of other endogenous cannabinoids (or endocannabinoids) were described, including 2-arachidonoylglycerol (2-AG), 2-arachidonoylglycerol ether (noladin ether), *N*-arachidonoyldopamine, and *O*-arachidonoyl ethanolamine (virodhamine) [see [10] for a review]. The structures of THC, anandamide, and 2-AG are depicted in Figure 18.1. Although the chemical structure of anandamide does not resemble the structure of classical cannabinoids such as Δ^9 -THC or of nonclassical synthetic cannabinoids, such as CP 55,940 [11] and the aminoalkylindoles [12], it shares with these diverse cannabinoids the ability to bind to and activate identified cannabinoid receptors and to produce a similar profile of pharmacological effects, although there are also some differences (see [13] for a review).

Another important tool in cannabinoid pharmacology was development of selective CB₁ and CB₂ cannabinoid receptor antagonists SR141716A (rimonabant, trade name Accomplia) and SR144528, respectively [14, 15]. The initial importance of these antagonists rested with their usefulness as tools in determining receptor mediation of cannabinoid effects. Subsequently, it was reported that SR141716A acted as an inverse agonist in certain *in vitro* tests, particularly at higher concentrations [16]. *In vivo*, SR141716A blocks most of the cannabinoid effects of plant-derived and synthetic cannabinoids; however, it also produces locomotor stimulation (opposite of the locomotor suppression produced by active cannabinoids) [17]. Tests

with a series of structural analogs of SR141716A indicated that this stimulatory effect did not show a systematic structure–activity relationship; hence, it is probably not CB₁ receptor mediated [18]. Currently, SR141716A has been approved in the United States as an anti craving agent for smoking cessation and is undergoing phase III clinical trials as an appetite suppressant.

While the initial focus of marijuana research was on understanding the abuse potential of this drug, increasing interest has been shown in medical marijuana as well as in the therapeutic implications of pharmacological manipulations of the endocannabinoid system through which marijuana acts. The possible physiological roles of this system are only now starting to be delineated. In the following sections, we describe the endocannabinoid system and its potential physiological roles as well as discuss the ways in which marijuana may interact with this system.

18.2 ENDOCANNABINOID SYSTEM

The endocannabinoid system is one of several lipid signaling systems in the brain and in the body. This system consists of four basic elements: (a) two identified receptors, (b) several derivatives of arachidonic acid that serve as endogenous ligands, (c) synthetic and degradative pathways for these endocannabinoids, and (d) signal transduction pathways. Each of these components contributes to the overall functioning of the signaling system and is discussed in further detail below. In addition, the endocannabinoid system is not static over the course of development. For this reason, a brief description of age-dependent changes that occur during early life is included.

18.2.1 Cannabinoid Receptors and Signaling

To date two cannabinoid receptors, CB₁ and CB₂, have been identified. A splice variant of the CB₁ receptor, CB_{1A}, has also been cloned [19], but its biological significance remains unknown. CB₁ receptors are located primarily in the brain (as discussed in greater detail later). In contrast, CB₂ receptors are located primarily (but not exclusively; see [20]) in the periphery and are involved in the immunoregulatory effects of cannabinoids [21, 22]. Δ^9 -THC binds with approximately equal affinity to both subtypes of receptors [23]. Recent research results have raised the possibility that additional non-CB₁, non-CB₂ receptor(s) may exist, although none has been definitively identified (see [24] for a review).

The largest concentration of CB₁ receptors is located in the central nervous system, although their presence has also been noted in other parts of the body. Autoradiographic studies have shown high levels of CB₁ receptor binding in the basal ganglia (substantia nigra pars reticulata, globus pallidus, entopeduncular nucleus, and lateral caudate putamen) and the molecular layer of the cerebellum [25]. Cannabinoid-induced motor impairment may be related to activation of CB₁ receptors in these regions. Intermediate levels of binding are present in the CA pyramidal cell layers of the hippocampus, the dentate gyrus, and layers I and VI of the cortex. These receptors are most likely responsible for cannabinoid effects on memory and cognition. CB₁ receptors are also present in the ventromedial striatum and nucleus accumbens, areas that are associated with dopamine and mediation of brain reward. Localization here is consistent with the observation that most drugs of

abuse (including marijuana) directly or indirectly modulate dopamine release in these brain regions. Sparse levels were detected in the brain stem, which likely explains the low respiratory depressant effects of cannabinoids.

The predominant centrally mediated effects of cannabinoids occur through activation of inhibitory G proteins ($G_{i/o}$ and/or G_i) coupled to CB_1 receptors [26], although there was a report that CB_1 receptors can couple to G_s proteins [27]. Binding and activation of CB_1 receptors by Δ^9 -THC, anandamide, and other cannabinoid agonists results in a number of intracellular signaling processes, including inhibition of adenylyl cyclase, inhibition of calcium channels (N and Q types), and activation of inwardly rectifying potassium channels [28, 29]. In addition, mitogen-activated protein kinases are activated by the CB_1 receptor [30]. Whether all signal transduction systems are activated simultaneously is not known nor is the extent to which they are involved in specific cannabinoid actions. In addition, recent evidence has demonstrated the presence of an allosteric binding site on CB_1 receptors that modulates the affinity and efficacy of exogenous cannabinoids [31]. The effects of binding to this site on modulation of endocannabinoid activity under physiological conditions remain unknown.

In most traditional neurotransmitter systems (e.g., monoamines), receptors may be either pre- or postsynaptic; however, one-to-one correspondence between specific neurons and the neurotransmitter that they release is the general rule. A unique aspect of the endocannabinoid system is that endocannabinoids are released from neurons that are associated with release of many other neurotransmitters, including dopamine, γ -aminobutyric acid (GABA), and glutamate [32]. CB_1 receptors are prevalent on presynaptic terminals of neurons associated with almost all known neurotransmitters. Activation of these receptors is modulatory with respect to release of the primary neurotransmitter. The complexity of cannabinoid modulation of neurotransmitter release is further illustrated by recent findings that endogenous cannabinoids may act in a retrograde signaling fashion [33]. In this process, depolarization of a postsynaptic neuron elicits release of an endocannabinoid such as anandamide from that neuron. Endocannabinoids have a direct inhibitory action on release; however, their presynaptic localization on neurons that release both excitatory and inhibitory neurotransmitters means that the end result of CB_1 receptor activation may be either inhibitory [if release of an excitatory neurotransmitter such as glutamate is inhibited; i.e., depolarization-induced suppression of excitation (DSE)] or excitatory [if release of an inhibitory neurotransmitter such as GABA is inhibited; i.e., depolarization-induced suppression of inhibition (DSI)]. Indeed, inhibition of release of a neurotransmitter that tonically regulates the release of another neurotransmitter can result in increased release of the latter. For example, cannabinoids are also known to stimulate the release of dopamine in the nucleus accumbens by inhibition of glutamate release.

18.2.2 Synthesis and Metabolism of Endocannabinoids

To date, at least three arachidonic acid derivatives that serve as endocannabinoid ligands have been identified: arachidonylethanolamide (anandamide [9]), 2-AG [34], and 2-arachidonoyl-glyceryl ether (noladin ether [35]). Two other endocannabinoid ligands, *N*-arachidonoyldopamine [36] and *O*-arachidonylethanolamine (virodhamine) [37], have also been proposed. Anandamide, by far, is the best characterized.

In the brain, anandamide binds to and activates CB₁ receptors, which, as described above, are G-protein-coupled receptors. Anandamide also interacts with transient receptor potential V1 (TRPV1) receptors and with a number of cation channels [38–40].

Synthetic and degradative pathways for endocannabinoids have been identified. Substantial evidence indicates that anandamide is formed from arachidonic acid that is bound to cell membranes. This process is calcium and energy independent and involves activation of a transacylase that transfers arachidonic acid from the *sn*-1 position of phosphatidylcholine to the amino group in phosphatidylethanolamine, with subsequent hydrolysis by a phospholipase-D-type enzyme [41]. Since anandamide is not stored in vesicles, it is synthesized and released on an “as-needed” basis. Inactivation of anandamide occurs primarily via degradation by fatty acid amide hydrolase (FAAH), an enzyme that also degrades a number of other endogenous fatty acids, including the sleep-inducing lipid oleamide [42]. This enzyme has been cloned [43]. In mice, potentiation of the actions of exogenously administered anandamide is observed with pharmacological blockade of FAAH with a FAAH inhibitor and with deletion of the gene encoding for FAAH [44]. Anandamide may also be inactivated in part through a specific uptake mechanism in which it is transported across cellular membranes by a protein-mediated process that has the characteristics of facilitated diffusion [i.e., bidirectional and sodium and adenosine triphosphate (ATP) independence] [45].

18.2.3 Development

In humans, most of the research into the effects of marijuana on development has concentrated on identification of possible marijuana-induced fetal and birth defects. To this end, epidemiological studies have revealed that the most consistent effect of maternal marijuana use is shortened gestation and reduced birth weights; however, few long-term developmental consequences have been noted in the offspring of mothers who smoked marijuana during pregnancy [46]. By and large, the effects that have been reported are subtle and most appear to be reversible. The major exception appears to be higher cognitive functioning (executive functioning) that is impaired for a sustained period of time in the children who were exposed in utero.

Much of what we know about the acute and long-term effects of marijuana on the developing brain was discovered in the course of preclinical research with Δ^9 -THC in rodents. Prenatal exposure studies in rodents have shown that high doses of cannabinoids can produce resorption, growth retardation, and malformations, but only at doses that also produced malnutrition, which has similar consequence [47]. Doses of Δ^9 -THC that do not alter maternal body weight produce little effect on fetal development. The results of a number of studies of postnatal exposure to Δ^9 -THC in rodents have also been published. Since rats are born at a more immature stage than are humans, the preweanling period of a rat's life most closely corresponds to prenatal development in humans. During the first month or so of a rat's life, the endocannabinoid system in the brain undergoes a number of important changes. CB₁ receptors in the rat brain exhibit a progressive increase in number, but not in affinity, during the preweanling period (i.e., before postnatal day 21) and during early adolescence (females peak at postnatal day 30 and males peak at postnatal day 40). Receptors are pruned and decline to adult levels during later adolescence [48–50]. By postnatal day 60, adult levels of cannabinoid receptors are achieved [48]. Increases

in levels of the endogenous cannabinoid anandamide and *N*-arachidonoyl-phosphatidylethanolamine (an anandamide precursor) accompany these changes in receptor number throughout development [51]. While most brain CB₁ receptors present during development are distributed similarly to adult receptors (e.g., high levels in striatum, cerebellum, and cortex), an early transient atypical localization in pre-synaptic white matter has also been observed, suggesting a role for the endogenous cannabinoid system in neuronal migration and brain development [52, 53]. In addition, functional brain CB₁ receptors and anandamide also play a crucial role in physical growth and development, as they are necessary for milk suckling [54]. Although similar experiments obviously cannot be performed in human children and adolescents, it has recently been recognized that the human brain also undergoes substantial reorganization during adolescence [55].

18.3 MARIJUANA PHARMACOLOGY: IMPLICATIONS FOR PHYSIOLOGY OF ENDOCANNABINOID SYSTEM

Marijuana is typical of most psychoactive substances in that it produces a broad array of behavioral and pharmacological effects, many of which are subjective and differ among users. Some of the more prevalent effects on the central nervous system include euphoria, sedation, dreamlike state, distorted perceptions of sensory information and time, disrupted cognition, and impairment of fine motor skills [56]. Δ^9 -THC produces the subjective "high" associated with smoking marijuana and represents the chemical basis for many of its other effects in the central nervous system.

In rodents, Δ^9 -THC, other plant-derived cannabinoids, and synthetic cannabinoids that bind to CB₁ receptors with reasonable affinity produce a characteristic tetrad of pharmacological effects in mice, including suppression of locomotor activity, hypothermia, antinociception, and catalepsy [57]. These psychoactive cannabinoids also produce Δ^9 -THC-like discriminative stimulus effects in rats and rhesus monkeys (for a review, see [58]). Among this group of cannabinoids, potencies for producing these effects are highly correlated with affinities for the CB₁ receptor [5], suggesting that these effects are mediated via interaction with this receptor. Further evidence for CB₁ receptor mediation of these pharmacological properties is seen in blockade of the effects by SR141716A [17, 59], but not by administration of the CB₂ antagonist SR144528 [60].

Anandamide and structural analogs of anandamide produce a profile of pharmacological effects in mice that resemble those produced by Δ^9 -THC; however, anandamide-like cannabinoids have lower efficacies for effecting hypothermia: Body temperature decreases are about half that of traditional cannabinoids [61–63]. Further, correlations between in vitro affinities of anandamide analogs for CB₁ receptors and their in vivo potencies were not as strong as for other classes of cannabinoids [64, 65]. Differences in anandamide pharmacology also have been noted in drug discrimination studies [66] as well as in the mechanism through which anandamide produces spinal antinociception in mice [63, 67, 68]. In addition, it was reported that anandamide's pharmacological effects were not blocked by the CB₁ antagonist SR141716A, although SR141716A blocked the cannabimimetic effects of more stable anandamide analogs, such as 2-methyl-2'-fluoroethylanandamide [69].

An issue of concern with respect to these differences in anandamide's pharmacological effects is the extent to which pharmacokinetics may play a role. As mentioned previously, FAAH rapidly hydrolyzes anandamide to arachidonic acid [70, 71]. In contrast, Δ^9 -THC and other plant-derived cannabinoids are metabolized primarily through the hepatic P_{450} system [72], a process which requires much more time. For the most part, studies that have addressed the extent to which the observed differences in anandamide pharmacology might be related to these differences in its biodisposition have suggested that many of the anomalies in anandamide pharmacology (as compared to that of traditional cannabinoids) are not observed when the metabolism of anandamide is slowed, as in FAAH knockout mice [44] or as a result of administration of an agent that inhibits FAAH [73, 74]. Nevertheless, differences in anandamide pharmacology that cannot be explained by its rapid metabolism remain (see [13] for a review), suggesting that the effects of exogenously administered cannabinoids (including marijuana) may not entirely mimic physiological activation of the endocannabinoid system. This caveat should be kept in mind throughout the following descriptions of specific areas in which endocannabinoid involvement is strongly implicated and in which marijuana has prominent pharmacological effects.

18.3.1 Pain

Interest in cannabinoids as analgesic agents began with cannabis before attention turned to Δ^9 -THC and finally the endogenous cannabinoid system. Noyes et al. [75] demonstrated that orally administered Δ^9 -THC elevated mood, stimulated appetite, and produced some analgesia in cancer patients at doses that also produced dizziness, blurred vision, and impaired thinking. They concluded that Δ^9 -THC and codeine had comparable efficacy [76], while other investigators found it to have little analgesic efficacy [77, 78]. There has also been a conscientious effort to develop synthetic cannabinoid derivatives that might be useful as analgesics, but they too have been hampered by their behavioral side effects [79, 80].

Evaluations of cannabinoids in animal models have consistently shown them to be antinociceptive [81]. However, the fact that Δ^9 -THC analgesia is also accompanied by other effects, such as motor depression, raised questions regarding the validity of these antinociceptive measures. However, Walker et al. [82] showed that cannabinoids suppress nociceptive neurotransmission at the level of the spinal cord and the thalamus and that the effects were selective for painful as opposed to nonpainful somatic stimuli. Earlier, it had been shown that intrathecal administration of either the α_2 -noradrenergic antagonist yohimbine [83] or the κ -opioid antagonist nor-binaltorphimine (nor-BNI) [84] blocked cannabinoid-induced antinociception but failed to attenuate cannabinoid-induced motor impairment. Furthermore, intrastriatal administration of cannabinoids into the caudate nucleus produced catalepsy [85] without producing antinociception [86]. Cannabinoids have also been shown to exhibit antinociception in several chronic-pain models. The synthetic cannabinoid agonist WIN 55,212-2 produced anti-hyperalgesic responses following a chronic constriction injury of the sciatic nerve [87]. Another study that employed an arthritic pain model using Freund's adjuvant found Δ^9 -THC to be antinociceptive in both arthritic and nonarthritic rats [88].

With the identification of the endogenous cannabinoid system, it became possible to establish the mechanism of cannabinoid-induced analgesia and to further delineate

between direct and indirect effects. Initial studies showed that exogenous administration of anandamide to mice [63, 89] and rats [90] was antinociceptive. This evidence coupled with observations that cannabinoids inhibit nociception [86, 91] when injected into brain areas associated with antinociception [92] and that contain cannabinoid receptors [93] suggested the presence of a cannabinoid system that functioned to modulate pain. Electrical stimulation of periaqueductal gray (PAG) induced CB₁-mediated analgesia and simultaneously released anandamide [94]. Also the injection of formalin into the paw induced a nociceptive response and concomitant release of anandamide from the PAG. In fact, an earlier investigation had suggested that an endocannabinoid tone may downmodulate pain perception via CB₁ receptors in another region of the brain stem, the rostral ventromedial medulla, through the same circuit previously shown to contribute to the pain-suppressing effects of morphine [95]. Calignano et al. [96] suggested an endocannabinoid and CB₁/CB₂-mediated tone controlling pain at the peripheral level, mostly based on the observation that local administration of the antagonist for each receptor subtype led to hyperalgesia, whereas exogenous anandamide blocked the painful response of mice to formalin injection. In a subsequent study, however, no difference with vehicle-treated rat paws was found in the amounts of anandamide and 2-AG in the hind paw of rats after injection of formalin and during the maximal nociceptive response [97]. These studies, taken together with that by Meng et al. [95] and Walker et al. [94], suggest that if endocannabinoids tonically modulate inflammatory pain perception they may do so at sites different from those of inflammation.

It is also well known that stress will induce antinociception. Suplita et al. [98] demonstrated that a descending cannabinergic neural system is activated by stress to modulate pain sensitivity in a CB₁ receptor-dependent manner. Furthermore, this pathway involves both brain stem rostral ventromedial medullar and midbrain dorsolateral PAG. Stress produces an elevation in both anandamide and 2-AG levels in the PAG, and SR141716 blocks the associated stress-induced analgesia [99]. These latter investigators provided further evidence for endocannabinoid involvement by demonstrating that inhibitors of monoacylglycerol lipase (degrades 2-AG) and FAAH (degrades anandamide) also enhance stress-induced antinociception when injected into the PAG. It had been shown previously that FAAH inhibitors greatly elevated anandamide levels in rodent brain and produced CB₁ receptor-dependent antinociception [100]. As mentioned above, it is logical to presume that a CB₁ receptor antagonist might produce hyperalgesia if elevation of anandamide produces antinociception. However, one study reported that SR141716 produced hyperalgesia in the hot-plate test [101], whereas another failed to show hyperalgesia to a mechanical stimulus in either nonarthritic or arthritic rats [88].

The first electrophysiological evidence that cannabinoids can block spinal pain pathways was the intravenous administration of WIN 55,212-2 that selectively suppressed noxious-evoked firing of the wide-dynamic-range (WDR) neurons to a noxious pressure stimulus [102]. Importantly, WIN 55,212-2 did not affect the stimulus-evoked activity of non-nociceptive neurons in the spinal cord. WIN 55,212-2 also inhibited noxious stimulus-evoked activity of neurons in the ventrolateral posterior nucleus of the thalamus [103]. Although these results demonstrated that cannabinoids suppress the ascending nociceptive pathway, they did not address the site of cannabinoid action in the central nervous system (CNS). Experimental evidence indicates that cannabinoids inhibit nociceptive responses at both spinal and

supraspinal sites. Intravenous administration of either Δ^9 -THC or CP 55,940 to spinally transected rats was found to reduce, but not eliminate, antinociception [104]. Direct injections of cannabinoids into the brain provided evidence for a supraspinal site of action [86, 105]. Direct administration of WIN 55,212-2 into the dorsolateral PAG or dorsal raphe nucleus, but not the ventral PAG, medial septal area, lateral habenula, arcuate nucleus, or perihypothalamic area, produced a partial antinociceptive effect [91]. Similarly, CP 55,940 infused into the posterior ventrolateral area in the region of the dorsal raphe produced antinociception as well as other pharmacological actions [86]. In contrast, drug administration into either dorsolateral or anterior ventrolateral PAG sites or outside of the PAG borders was without effect.

Many antinociceptive drugs acting in the brain activate descending neurochemical systems to inhibit the input of noxious stimuli at the spinal level. Spinal noradrenergic and serotonergic fibers are believed to play a predominant role in the antinociceptive effects of a variety of drugs. There is evidence suggesting the involvement of monoaminergic systems in cannabinoid-induced antinociception. Both 5,7-dihydroxytryptamine [106], a serotonergic neurotoxin, and 6-hydroxydopamine [107], a dopaminergic neurotoxin, reduced the antinociceptive effects of cannabinoids. Other evidence implicating the involvement of norepinephrine in cannabinoid-induced antinociception is that intrathecal (i.t.) administration of the α_2 -noradrenergic antagonist yohimbine blocked the antinociceptive effects of intravenous (i.v.)-administered Δ^9 -THC [83]. In contrast, i.t. injection of the nonspecific serotonin antagonist methysergide failed to reduce Δ^9 -THC-induced antinociception. These findings are consistent with the hypothesis that the supraspinal component of cannabinoid-induced antinociception is mediated through a descending spinal noradrenergic system. There is also evidence that GABA_B receptor agonists produce antinociception through modulation of the endocannabinoid system at the spinal level. SR141716 blocked the antinociceptive effects of baclofen but the, GABA_B antagonist saclofen did not block the analgesic effects of CP55940 [108].

Recently, attention has turned to the CB₂ receptor as an important target for regulation inflammation and the pain associated with it. The CB₂ selective agonist HU-308 reduced formalin-induced pain and arachidonic acid-induced inflammation (ear swelling) [109]. Another CB₂ selective agonist, AM1241, has been reported to be anti-inflammatory and analgesic in several pain models [110]. The nonselective agonist CP 55940 was reported to be effective in a neuropathic pain (spinal nerve ligation) model, and its effects were blocked only by the CB₂ receptor antagonist [111]. Valenzano et al. reported that a selective CB₂ receptor agonist was active in neuropathic, incisional, and chronic inflammatory pain models and was inactive in CB₂ receptor knockout animals [112]. Moreover, CB₂ receptors were upregulated in dorsal root ganglia (DRG) following sciatic nerve section or spinal nerve ligation [113].

TRPV1 represents another possible target for cannabinoid action. Jerman et al. demonstrated that anandamide caused a concentration-dependent increase in intracellular calcium concentrations in VR1-HEK (human embryonic kidney) and DRG cells that was blocked by capsazepine but not by SR141716 [114]. The authors concluded that anandamide analgesic properties are likely to be mediated at least in part through TRPV1 activation. Lam et al. also found that anandamide was a partial agonist in increasing intracellular concentrations in TRPV1-containing HEK cells, but they did not report whether its effects were blocked by capsazepine [115].

Unfortunately, there is little *in vivo* evidence that anandamide antinociception is mediated through TRPV1, in part because TRPV1 antagonists are typically not very effective when administered to animals. Capsazepine does not attenuate cannabinoid stress-induced analgesia [98]. There are suggestions that hybrid anandamide/capsaicin analogs may produce some of their antinociceptive effects through TRPV1, but direct evidence is lacking [116].

18.3.2 Cognition

One of the most prominent behavioral effects of Δ^9 -THC and other psychoactive cannabinoids is disruption of cognition. This effect has been observed in humans and in animal models. In human marijuana users, smoked marijuana interferes with the ability to learn and recall verbal information and it impairs short-term memory [117–119]. In addition, smoked marijuana disrupts timing ability in experiments requiring subjects to estimate elapsed time. Subjects in these experiments responded prior to completion of the specified time interval, suggesting overestimation of elapsed time [120, 121]. Similar impairments of short-term (i.e., working) memory and timing ability have been observed in animal models (see [122] for a review). Rodents injected with an acute dose of a psychoactive cannabinoid exhibited impairments in recognition memory as well as delay-dependent deficits in accuracy in delayed match/nonmatch to sample procedures and in spatial water and land maze tasks [123–126]. CB₁ receptor mediation is indicated, as these effects were reversible upon elimination of the drug or administration of SR141716A and were not evident in CB₁ knockout mice [127]. Interestingly, memory impairment produced by Δ^9 -THC in a delayed match-to-sample task was accompanied by decreases in firing rates of hippocampal neurons during the sample, but not the match, phase of the experiment, suggesting that, at least for this task, Δ^9 -THC disrupts encoding of memories during the sample phase, but not their retrieval during the match phase [124]. Δ^9 -THC-induced dopamine hyperactivity in the prefrontal area also has been implicated in some types of observed memory impairments [128]. While cannabinoids affect acquisition (i.e., learning) to a lesser degree than they do working memory, acquisition of new information *is* impaired. For example, Δ^9 -THC increased the number of errors made by rats working in a repeated acquisition task [129]. In contrast, long-term memory is relatively unaffected in both humans [130] and animals [122] following cannabinoid administration, suggesting cannabinoid interference with only certain types of cognition.

In addition to inducing selective cognitive impairments, Δ^9 -THC is reported to produce severe disruption of timing and temporal discrimination in rodents. Consistent with results of human studies with smoked marijuana [120], peripherally injected Δ^9 -THC impaired performance of rats responding for food reward under differential reinforcement of low rates (DRL) operant schedules [131, 132]. In this type of schedule, an animal is required to wait for a specified length of time since the last response before responding will again be reinforced; that is, the interresponse time (IRT) must be of a specified minimum length. Under conditions in which the specified IRT was short (5 s or less), Δ^9 -THC had no effect on the pattern of responding; however, when the target wait time was lengthened to 10–15 s, premature responding was observed. Collectively, the results of both human and rodent studies suggest that Δ^9 -THC disrupts timing by making longer delays seem shorter.

Conversely, Han and Robinson [133] found that SR141716A increased estimated time in another type of operant procedure, raising the possibility that it may do so by blocking endogenous anandamide.

Cannabinoid effects on learning, working memory, and temporal discrimination occur within the range of doses that are intoxicating in humans and that produce discriminative stimulus effects in animals, but at doses lower than those required to elicit other characteristic cannabinoid effects (e.g., motor suppression, analgesia, and hypothermia). This separation of effects suggests a degree of selectivity for cannabinoid effects on higher functioning.

Results of studies that involved CB₁ receptor nullification (e.g., pharmacological blockade, genetic manipulation) have suggested a possible physiological role of endocannabinoids in cognition. Selective antagonism of CB₁ receptors with SR141716A delayed extinction in a previously learned water maze task in mice at doses that did not affect swim speeds, and mice lacking CB₁ receptors exhibited a similar delay in extinction in this task [127]. In each case, CB₁ receptor nullification increased perseveration in a previously learned behavior. These findings may result from interference with cognitive processes related to forgetting (e.g., memory duration) and/or to suppression of behavior (i.e., extinction). If increased memory duration were the primary factor effecting perseveration, the delay between acquisition of a behavior and its recall would be most important to performance (i.e., perseveration would occur at short delays and would be independent of number of trials). In contrast, a primary deficit in extinction would evince less perseveration with increasing number of trials. In a study that varied number and spacing of trials, SR141716A-induced perseveration was most apparent in extinction trials that occurred infrequently (spaced trials) versus those that occurred consecutively on the same day (massed trials) [134]. Although these results seem to suggest that SR141716A's primary effect was on extinction, its effects on forgetting could not be assessed adequately due to the extended duration of memory in the control group. Given that SR141716A produced its pharmacological effects on cognition at doses that have not been associated with inverse agonism at CB₁ receptors, antagonism of endocannabinoid action at these receptors is the most likely mechanism. However, while it is tempting to speculate that endocannabinoids tonically modulate the neural pathways that underlie cognition, empirical results supporting this hypothesis are still inconclusive.

18.3.3 Appetite Regulation

Marijuana increases appetite in humans, which was recognized even in historical accounts. Indeed, this effect serves as the basis for development of oral formulations of Δ^9 -THC that are currently in therapeutic use to treat cachexia in cancer and AIDS patients [135, 136]. As in humans, Δ^9 -THC and other psychoactive cannabinoids increase food intake in rodent models, as does exogenously administered anandamide [137–139]. This effect is blocked by coadministration of SR141716A (but not SR144528) and is not observed in CB₁ knockout mice [140–142]; hence, it appears to be CB₁ receptor mediated. Further, SR141716A and several of its analogs produce effects on feeding that are opposite those of cannabinoid agonists; that is, they dose-dependently decrease food consumption in rodents [141, 143, 144], and in clinical trials in humans SR141716A produces weight loss [145].

In humans and other mammals, food intake is a complex physiological process that is regulated by both homeostatic mechanisms and the hedonic value of food. Endocannabinoid involvement is implicated in both types of regulation [146], as anandamide levels in both the hypothalamus (associated with homeostatic mechanisms) and limbic forebrain (associated with hedonics of food intake) are increased in hungry rats and return to basal levels when rats are satiated [147]. The hypothalamus is a major player in homeostatic control of appetite, and it is here where endocannabinoids exert their primary central effects on this type of regulation of food intake. Although the hypothalamus does not have many CB₁ receptors as compared to other areas rich in these receptors (e.g., hippocampus), those that it has appear to be very efficient at activating intracellular messenger systems. An increase in hypothalamic anandamide levels, through either endogenous release or exogenous administration directly into the hypothalamus, acts to stimulate eating [148].

Of course, the endocannabinoid system is but one of the many neuromodulatory systems that affect food intake (e.g., [149]). For example, the hormone leptin is a key regulator of feeding behavior that is found mainly in white adipose tissue. Upon feeding, it is released into the circulation. Once leptin reaches the hypothalamus, it initiates a series of signaling events that eventually leads to release of anorexigenic peptides (e.g., pro-opiomelanocortin and cocaine- and amphetamine-regulated transcript) or orexigenic peptides (e.g., neuropeptide Y and agouti-related protein). Leptin also exerts negative control over levels of anandamide and/or 2-AG in the hypothalamus [140]. Further, these investigators found higher levels of hypothalamic endocannabinoids in obese mice and rats with congenitally disrupted leptin signaling.

Endocannabinoids may also play a direct role in lipid metabolism in the periphery via activation of CB₁ receptors in adipocytes [150]. Blockade of these receptors by rimonabant stimulated Acp30 (adiponectin) messenger RNA (mRNA) expression in adipose tissue and reduced hyperinsulinemia in obese (*fa/fa*) rats [151]. These findings suggest that inactivation of the endocannabinoid system may aid weight loss by altering energy balance and lipid metabolism, an hypothesis that has recently received additional support at the genomic level in a diet-induced obesity model in rats [152].

In addition to their roles in homeostatic control of eating, however, endocannabinoids also may be involved in regulation of the hedonic value of food (via action in brain areas associated with reward; e.g., nucleus accumbens and limbic forebrain). Levels of anandamide and 2-AG in these reward-associated areas were increased during food restriction and returned to baseline when rats were satiated, much as they were in the hypothalamus under similar conditions [147, 153]. Yet, other feeding-induced changes in endocannabinoids in these reward areas were not associated with similar changes in the hypothalamus. Whereas significant decreases in CB₁ receptor density in the hippocampus, cortex, nucleus accumbens, and entopeduncular nucleus were observed in rats fed palatable food to induce obesity, changes in the density of hypothalamic CB₁ receptors were not noted [154]. Down-regulation of cannabinoid receptors in reward areas in obese rats were hypothesized to be the result of prolonged elevation of endocannabinoid levels in these areas. The fact that these region-specific differences in CB₁ receptor density were selectively induced in obese rats by a taste-enhanced diet, and not by a normal laboratory rodent diet, suggests a special sensitivity to the hedonic aspects of food in these reward-associated areas. These areas also appear to mediate the hedonic effects of drugs of abuse (including marijuana), although the degree to which the rewarding

properties of food and drugs involve similar mechanisms within these areas is still unclear. Nevertheless, it is intriguing that SR141716A, which was originally marketed as a pharmacological aid for smoking cessation, has also been shown to be effective in decreasing intake of palatable food.

18.3.4 Neurotoxicity

There has been considerable interest in the influence of cannabinoids on neuronal excitability and toxicity that may have relevance to several disease states. Δ^9 -THC has been shown to have both convulsant and anticonvulsant properties depending upon the model. Δ^9 -THC will enhance kindling elicited by either chemical or electrical stimuli [155], whereas it will decrease maximal electroshock-induced tonic-clonic convulsions [156]. The observation that cannabidiol, a structurally related cannabinoid lacking affinity for CB₁ receptors, is also anticonvulsant [157] raises the question of mechanism of action. There are several lines of evidence indicating that the endogenous cannabinoid system is capable of regulating neuronal excitability. The anticonvulsant effects of Δ^9 -THC in the maximal electroshock procedure is blocked by the CB₁ receptor antagonist SR141716, while the anticonvulsant effects of cannabidiol are not [158]. Subsequent studies demonstrated that anandamide and one of its stable congeners were also anticonvulsant and that a CB₁ receptor antagonist lowered electroshock seizure threshold [159]. Collectively, these observations suggest disruptions in endogenous cannabinoid tone can result in altered neuroexcitability.

The endocannabinoid system also influences the rat pilocarpine model of epilepsy. Cannabinoid receptor agonists completely blocked spontaneous epileptic seizures in this model, whereas the CB₁ receptor antagonist SR141716A increased both seizure duration and frequency [160]. Furthermore, levels of 2-AG were increased significantly within the hippocampal brain region during seizures, and Western blot and immunohistochemical analyses revealed that CB₁ receptor protein expression was significantly increased throughout the CA regions of the hippocampus of epileptic animals [160]. Similar results were obtained in animals lacking CB₁ receptors in that they exhibited increased kainic acid-induced seizures, and kainic acid increased hippocampal levels of anandamide in wild-type mice [161]. These investigators concluded that the endogenous cannabinoid system provides on-demand protection against acute excitotoxicity in the CNS. One possible explanation for cannabinoid protective effects is the presence of CB₁ receptors on excitatory glutamatergic neurons. Activation of these receptors decreases glutamate release and therefore decreases excitotoxicity [162].

As for a possible explanation for convulsant effects of cannabinoids, it has been suggested that exogenous cannabinoids, such as Δ^9 -THC, might also activate CB₁ receptors on inhibitory GABAergic neurons, leading to a decreased release of GABA and a concomitant increase in seizure susceptibility [162]. There is also evidence that anandamide itself can be proconvulsive. FAAH(−/−) mice exhibit increased sensitivity to kainic acid [163]. Administration of anandamide dramatically augments the severity of kainic acid-induced seizures in FAAH(−/−) mice but not in wild-type mice and enhanced neuronal damage in the CA1 and CA3 regions of the hippocampus. These findings do not support a general neuroprotective role for endocannabinoids in response to chemical-induced excitotoxicity. On the other hand, inhibition of FAAH

by organophosphates did not lead to any overt neurotoxicity or change in behavior despite elevating anandamide levels [164].

A number of *in vitro* studies support an anticonvulsant mechanism of action for cannabinoids. WIN 55,212-2 attenuated low-magnesium-induced burst firing in hippocampal culture [165], and both anandamide and 2-AG decreased stimulation-induced population spikes and low-magnesium-induced epileptiform discharges in rat hippocampal slice preparations [166]. The mechanism underlying this dampening of excitability is believed to involve inhibition of presynaptic glutamate release [165]. However, in fever-induced seizures, there is an increase in the number of CB₁ receptors associated with cholecystokinin-containing perisomatic inhibitory inputs, no effect on glutamate release, and enhanced retrograde inhibition of GABA release [167]. These results suggest that inhibition of GABA rather than glutamate release is important for febrile seizures. *In vitro*, there is evidence that endocannabinoids act in a retrograde manner to produce depolarization-induced suppression of inhibition by suppressing GABA release and thus disinhibiting pyramidal neuronal activity [168]. As such it would be expected that endocannabinoids would be excitotoxic.

As for general neurotoxicity, Chan et al. reported that Δ^9 -THC caused shrinkage of neuronal cell bodies and nuclei and genomic DNA strand breaks [169]. Δ^9 -THC also stimulated release of arachidonic acid leading to speculation that Δ^9 -THC's mechanism for neurotoxicity involves arachidonic acid metabolism to prostanoid synthesis and generation of free radicals by cyclooxygenase. Δ^9 -THC induces apoptosis in cultured cortical neurons through activation of both c-Jun N-terminal protein kinase isoforms JNK1 and JNK2 [170].

On the other hand, endocannabinoids inhibit A β toxicity, and this protective effect was prevented by the CB₁ receptor antagonist [171]. Anandamide's effects appear to be mediated through the mitogen-activated protein kinase pathway. The observation that cannabinoids retained their antioxidative properties in cultured cerebellar granule cells derived from either CB₁ receptor knockout mice or control wild-type littermates suggests that the CB₁ receptor is not involved in the cellular antioxidant neuroprotective effects of cannabinoids [172]. The specificity of cannabinoid neuroprotection is subject to further question when non-CB₁ receptor cannabinoids such as cannabidiol also produce neuroprotection. Cannabidiol protects against hippocampal and entorhinal cortical neurodegeneration in a dose-dependent manner [173]. Earlier studies had also found Δ^9 -THC and cannabidiol to be equally effective in preventing hydroperoxide-induced oxidation [174].

The role of the endogenous cannabinoid system in neuronal excitation and toxicity remains to be resolved. It appears that the endocannabinoids are capable of exerting both protection and causation of toxicity depending upon the neuronal insult. This possible dual action may arise from the ability of endocannabinoids to alter the release of both excitatory and inhibitory neurotransmitters.

18.3.5 Emesis

Several animal studies indicate a direct role for endocannabinoid modulation of emesis. Darmani et al. [175] showed that CB₁ receptor agonists reduced cisplatin-induced emesis in the least shrew while the antagonist rimonabant produced the opposite effects. Similar findings were reported with cannabinoid agonists that attenuated lithium-induced vomiting in the musk shrew [176, 177]. In addition, combinations of

inactive doses of Δ^9 -THC and ondansetron were effective in blocking vomiting in the musk shrew [177]. The musk shrew has also been used to study conditioned retching, an animal model of anticipatory nausea and vomiting. Δ^9 -THC completely suppressed conditioned retching in this model [178]. In addition, cannabinoid agonists suppressed lithium-induced conditioned rejection, a model of nausea in rats [179]. Opioids are known to be powerful emetogenic agents. Activation of the cannabinoid system was also effective in blocking opioid-induced vomiting in ferrets [180]. CB_1 receptors were strongly implicated in that rimonabant blocked the action of cannabinoid agonists in this model. Importantly, Darmani et al. [181] found prominent CB_1 receptor binding in the nucleus tractus solarius of the shrew. Van Sickle et al. demonstrated that cannabinoid agonists inhibited emesis and retching in ferrets whereas CB_1 receptor antagonists potentiated emetic responses [182]. Moreover, these investigators found both CB_1 receptors and FAAH in dorsal vagal complex consisting of the area postrema, nucleus of the solitary tract, and dorsal motor nucleus of the vagus in the brain stem. In addition, the CB_1 receptor was also found in the myenteric plexus of the stomach and duodenum. The antiemetic effects of Δ^9 -THC in ferrets were reported to be mediated selectively via the CB_1 receptor [183]. Evidence in the shrew suggests that cannabinoids act both presynaptically and postsynaptically in both central and peripheral serotonergic neurons to block emesis [184] as well as at D_2/D_3 dopaminergic receptors [185].

The recent discovery of CB_2 receptors in the dorsal motor nucleus of the vagus led to speculation that they may be involved in emesis [20]. However, CB_2 selective agonists failed to inhibit emesis in ferrets. On the other hand, 2-AG reduced emesis in ferrets, an effect that was attenuated by administration of both CB_1 and CB_2 antagonists, leading the authors to conclude that if CB_2 receptors are indeed involved in emesis, they require the presence of CB_1 receptors. Finally, a metabolically stable analog of anandamide blocked vomiting, whereas another endocannabinoid, 2-AG, was emetogenic in shrew [181], suggesting possible species differences in the effects of endocannabinoids on emesis.

As for clinical evidence, anecdotal reports of patients smoking marijuana to control chemotherapy-induced nausea and vomiting provided the initial clues. These reports led to clinical studies with Δ^9 -THC in which it was found to be useful in patients whose chemotherapy-induced nausea and vomiting were refractory to other standard antiemetics available at that time [186]. Plasse et al. [187] reported that combinations of Δ^9 -THC and prochlorperazine resulted in enhancement of efficacy as measured by duration of episodes of nausea and vomiting and by severity of nausea. In addition, the incidence of psychotropic effects from Δ^9 -THC appeared to be decreased by concomitant administration of prochlorperazine. The combination was significantly more effective than was either single agent in controlling chemotherapy-induced nausea and vomiting [188]. Nabilone, a synthetic derivative of Δ^9 -THC, was also reported to be an effective oral antiemetic drug for moderately toxic chemotherapy [189]. Cannabinoids have also been found to be effective in treating nausea and vomiting in children undergoing chemotherapy [190, 191]. As for the current status of antiemetics, serotonergic antagonists such as ondansetron have become the standards for managing emesis. These agents have proven to be effective in preventing chemotherapy-induced nausea and vomiting in most patients. However, delayed nausea and vomiting are less well controlled. Therefore, the search for more effective agents continues. Combination therapy with ondansetron and

Δ^9 -THC has not been fully explored. In addition, there is a need for a higher efficacy CB₁ receptor agonist with fewer side effects.

18.4 ENDOCANNABINOID ROLE IN REWARD, TOLERANCE, AND DEPENDENCE

With the exception of medical marijuana use, most people who have experienced the psychoactive effects of cannabinoids did so through voluntary self-administration of smoked or oral marijuana for the sole purpose of becoming intoxicated. Laboratory animals (including rats, mice, pigeons, and monkeys) can also detect the distinctive psychoactive effects of cannabinoids in drug discrimination, an animal model of these subjective effects [6, 58]. Moreover, monkeys and rats find cannabinoids reinforcing and will self-administer them under appropriate experimental conditions [192–194]. SR141716A blockade of the discriminative stimulus and reinforcing properties of cannabinoids in both humans and animals implicates direct CB₁ receptor mediation in cannabinoid intoxication and reward [194–196]; however, as with most other abused substances, indirect alteration of dopamine neurotransmission in brain reward areas [e.g., ventral tegmental area (VTA) and nucleus accumbens (NAc)] is also involved (for a review, see [197]).

Several mechanisms through which neural functioning in reward-related areas is affected by cannabinoids have been identified. First, peripherally administered Δ^9 -THC directly increased dopamine levels in the NAc in a calcium-dependent manner, an effect that was blocked by SR141716A as well as by preventing generation of action potential by administration of the sodium channel blocker tetrodotoxin [198, 199]. Second, Δ^9 -THC preferentially increased burst activity of dopamine neurons in the VTA [200, 201]. Since CB₁ receptors are not localized in the VTA, this increase is probably mediated via disinhibition of local GABA circuitry [202, 203], perhaps by a mechanism similar to that responsible for depolarization-induced suppression of inhibition. Third, although the exact mechanism is unclear, opioid mechanisms also play a role in cannabinoid modulation of reward pathways, as indicated by reversal of cannabinoid effects by administration of the opioid antagonists naloxone and naloxonazine [198, 204]. Interestingly, regulation of dopamine activity in reward-associated brain areas by cannabinoids may be bidirectional. Whereas research has shown that exogenous cannabinoids increase dopamine activity via several mechanisms (as described above), there is also evidence that dopamine activity affects endocannabinoid levels (anandamide and/or 2-AG) in limbic forebrain and prefrontal areas through intermediate glutamatergic mechanisms [205]. Further research is needed to elucidate completely all of the various mechanisms through which endocannabinoids play a role in the regulation of neural transmission in reward-related areas.

Although initial exposure to marijuana may be unpleasant, individuals who continue to use typically find the acute effects of marijuana rewarding, at least in the short term (most likely due to its effects on dopamine neurotransmission; see above). By definition, however, abuse involves repeated or chronic administration. Repeated administration of Δ^9 -THC and other psychoactive cannabinoids results in the development of profound tolerance (up to 100-fold) and cross tolerance to most cannabinoid effects in a number of animal species, including pigeons, rodents, dogs, monkeys, and rabbits (see [206] for a review). Pharmacodynamic events appear to

play the primary role in cannabinoid tolerance, as pharmacokinetic parameters (absorption, distribution, metabolism, and excretion) are relatively unaltered by chronic administration. Further, cross tolerance between Δ^9 -THC and anandamide-like cannabinoids has been reported to develop under certain circumstances, even though the primary metabolic pathways for these two classes of cannabinoids differ dramatically [207–209]. Pharmacodynamic tolerance is also indicated by the fact that the brains of cannabinoid-tolerant animals show profound CB₁ receptor down-regulation and reduced second-messenger signaling [210, 211].

Dependence also occurs with chronic exposure to cannabinoids, albeit it is somewhat more difficult to measure than for some other drugs of abuse (e.g., opioids). Dependence implies the presence of symptoms of withdrawal with abrupt termination following a period of chronic administration. Although a few reports have noted behavioral changes indicative of spontaneous withdrawal upon abrupt cessation of cannabinoids, heroic doses or continuous-infusion methods are typically required [212]. Most studies assessing cannabinoid dependence have used precipitated withdrawal. In this approach, dependent animals that have been chronically treated with a psychoactive cannabinoid are administered an antagonist such as SR141716A. Symptoms of precipitated withdrawal in rats and mice chronically infused with Δ^9 -THC and then administered SR141716A included head shakes, facial tremors, tongue rolling, biting, wet-dog shakes, eyelid ptosis, facial rubbing, paw treading, retropulsion, immobility, ear twitch, chewing, licking, stretching, and arched back [213–215]. This syndrome was reversed by readministration of Δ^9 -THC [216]. These studies provide convincing evidence that cannabinoids can produce dependence and are consistent with clinical observations of marijuana dependence [217]. Nevertheless, the marijuana dependence syndrome is milder than that typically reported for opioids and psychomotor stimulants.

18.5 FUTURE DIRECTIONS

The discovery of the endogenous cannabinoid system makes it possible to conduct a systematic evaluation of the effects of marijuana and its constituents in order to discern their direct and indirect effects. It appears that most of the recreational and medicinal effects of marijuana are produced through the endogenous cannabinoid system. However, the discovery of this system has provided an exciting new avenue for exploring a wide range of physiological functions and new development strategies for treating disease. The endocannabinoid system is best described as a modulator of other systems, thereby adding to the complexity of defining its physiological roles. In the future, it is likely that our knowledge of the endocannabinoid system will expand with the identification of additional receptor subtypes and endogenous ligands and with a better understanding of how it modulates other biological systems.

The abuse liability of opiates was recognized and written about as early as the sixteenth century. Abuse of and tolerance to opiates were described in manuscripts from Turkey, Egypt, Germany, and England [1]. Abuse of and dependence on opiates continue to represent a worldwide problem that is associated with significant morbidity and mortality. According to the World Health Organization, almost 13 million people abused opiate drugs in the years 1999–2001 [2].

Opiate abuse and dependence are associated with significant morbidity and mortality. Morbidity associated with opiate addiction includes the risk of contracting acquired immunodeficiency syndrome (AIDS) and hepatitis C infections from unsafe injection practices and high-risk sexual practices. The worldwide human immunodeficiency virus (HIV) epidemic continues at a rapid pace. Of the estimated 40 million people infected with HIV, 5 million were infected during 2003. In regions of the world where the infection is spreading the fastest, drug injectors and their sexual partners account for most of the new infections [3]. The U.S. Centers for Disease Control and Prevention (CDC) estimates that 36% of the AIDS cases in the United States are due to injection drug use or sexual activity with an injection drug user. Chitwood et al. [4] compared HIV infection prevalence across new injectors, long-term injectors, and heroin sniffers. The new injectors and the heroin sniffers had

prevalence rates of 13.3 and 12.7%, respectively, whereas the long-term injectors had a 24.7% prevalence rate. The attributable HIV risk from injection was 5.8% for the new injectors versus 55% for the long-term injectors. These data suggest that sexual risk factors play a major role in the spread of HIV into the general population in the new-injector and sniffer groups. The injection drug-using population is a significant contributor to the AIDS epidemic, suggesting that curtailment of the epidemic will not occur until this population is successfully treated for drug use and effectively counseled regarding unsafe sexual practices. Moreover, noninjection heroin users who are HIV positive also can contribute to the HIV epidemic by sexual transmission to their partners [5, 6].

Hepatitis C infections generally have a higher prevalence than HIV in injection drug users. Many infections occur early in the course of injection drug use. Garfein et al. [7] reported a 65% incidence of hepatitis C infection in a population with a one-year or less history of injection drug use. Over 95% of injection heroin users found to have significant liver disease in an early cohort (late 1970s and early 1980s) were later retrospectively found to have hepatitis C infection [8, 9]. Injection drug users infected with hepatitis C in this era will soon be or are already presenting with need for treatment and possible hepatic transplantation since 20% of hepatitis C-infected persons will progress to severe liver disease over a 20-year period of time. Of considerable concern, a very recent study has shown that essentially all of the former heroin addicts in methadone maintenance treatment who are HIV positive, and thus require treatment of AIDS infection, also have markers indicating prior or current hepatitis C infection [10]. Sixty-seven percent of the cohort were hepatitis C positive and 29% were HIV positive. Coinfection rates for the overall study group were 26%. HIV-hepatitis C virus (HCV) coinfection increases the progression of HCV-induced liver disease, resulting in faster progression to cirrhosis and end-stage liver disease [11]. Mortality increases from liver disease in HIV-HCV coinfecting patients have been reported [12].

“All-causes mortality” is high in untreated opiate-addicted populations. Desmond and Maddux [13] reported death rates in the illicit opiate-using population not in treatment ranged from 1.65 to 8.3% per year; the median yearly death rate was 3.5%. HIV disease has also impacted mortality and causes of mortality in this population. Quaglio et al. [14], analyzed heroin-related deaths in northeast Italy occurring from 1985 to 1998. Of the 2708 deaths, 37% were due to overdose and 32.5% were AIDS related. The mortality rate among the injection drug users (IDUs) was 13 times that of the general population. The effect of HIV infection on mortality in heroin users was also evaluated in the Vancouver Injection Drug Users Study [15]. Irrespective of HIV status, the leading cause of death was opiate overdose, accounting for 42% of the HIV-negative deaths and 25% of the HIV-positive cohort deaths. Of the 65 deaths among the HIV-positive group, 34% were AIDS related.

19.1 INCIDENCE AND PREVALENCE OF HEROIN AND PRESCRIPTION OPIATE ABUSE

The prevalence of heroin use is greater in developed countries; 2% of youth in western Europe, Canada, and the United States have tried heroin [2]. Moreover, the “purity” of heroin in the United States has increased significantly and the price has

fallen in the last 25 years from 7% in 1980 to an average of 51% in 2001 [16]. Heroin purity as high as 72% has been noted in Philadelphia. The change in purity has allowed a shift from intravenous use to intranasal use. The intranasal route is an acceptable route of administration for many heroin initiates. In fact, it is considered the method of choice for American adolescents [17]. Peak blood levels from intranasal use occur in 5 min, essentially equal to that seen with intramuscular injection [18]. The average age at which heroin was first used has dropped from 27 in 1988 to 19 in 1995 [17]. Use by the intranasal route tripled between 1991 and 1995. There is evidence that adolescent admission for heroin abuse and dependence tripled from 1993 to 1998 (see Section 19.2). One report noted that the average age was 17 years old for admission to treatment for heroin abuse [19]. For an overview of adolescent heroin abuse, see the review of Hopfer et al. [20]. There is also evidence that a significant percentage of heroin “snorters” will shift to injection [5, 6, 21].

Global statistics on the abuse of prescription opiates are unavailable. In the United States, incidence and prevalence rates of abuse of prescription opiates were obtained in the 2003 National Survey on Drug Use and Health (NSDUH) [22]. This survey is the primary source of information on illicit drug and alcohol use for the civilian, noninstitutionalized U.S. population aged 12 or older. In 2002, there were 2.5 million new users who endorsed nonmedical use of opiate analgesics. This is approximately a fivefold increase since 1990. (Another database, The Monitoring the Future study, a survey that questions 8th, 10th, and 12th graders about their drug use, has also noted a threefold increase in prescription opiate abuse since 1991 [23]). Fifty-five percent of the new users were females and 56% were age 18 or older. Individuals that were current users of opiate analgesics taken nonmedically totaled 4.7 million. It is doubtful that all of these individuals would meet the criteria of the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) for an opiate abuse diagnosis. In terms of lifetime prevalence, over 31 million Americans have used opiate analgesics in a nonmedical fashion. Opiate medications used most often in the survey were hydrocodone combinations (15.7 million), oxycodone combinations (10.8 million), hydrocodone (5.7 million), OxyContin (2.8 million), methadone (1.2 million), and Tramadol (186,000). When survey respondents were diagnosed using DSM-IV criteria, 57.4% of the heroin users met criteria for opiate abuse or dependence whereas 12.2% of the prescription opiate users met criteria for opiate abuse or dependence.

These data suggest that although there is a greater prevalence of prescription opiate abuse, the risk of dependence is lower in the population that abuses prescription opiate medications. Moreover, the data suggest an increasing problem with dependence on prescription opiates. Assuming one-eighth of the current nonmedical prescription opiate users meet DSM-IV criteria for abuse or dependence, that would equate to 600,000 people currently in need of treatment. Given the increasing incidence of nonmedical use of prescription opiates, the current situation is likely to worsen before it gets better.

Opiate abusers can be categorized into three groups: those abusing only heroin, those abusing only prescription opiates, and those abusing heroin and prescription opiates. An analysis of heroin, oxycodone, and heroin and oxycodone users was conducted in the 2003 NSDUH. Heroin and heroin-plus-oxycodone users had a 2:1 male-female ratio whereas the oxycodone-only group had more females (57:43). The majority of users of oxycodone, either alone or in combination with heroin, were

white (91%). Groups using heroin, either alone or in combination, were older than 35, whereas the majority (56%) of the oxycodone users were younger than 35. Past-year dependence diagnoses were 4, 16, and 7% for heroin, heroin plus oxycodone, and oxycodone alone, respectively.

In 2003, the NSDUH estimated that 19.5 million Americans were current illicit drug users (use within 30 days of the NSDUH survey). Of these, 3.8 million were considered to meet criteria for abuse or dependence and another 3.1 million were diagnosed with abuse or dependence to alcohol and illicit drugs. When alcohol use alone is added to these categories, 21.6 million people aged 12 or older were classified with a substance abuse disorder. Of this group, 3.3 million sought treatment in 2003. In terms of opiate users, 415,000 prescription opiate users and 281,000 heroin users sought treatment.

The treatment of opiate addiction can be conceptualized as occurring in three categories: discovery of new therapies, development of new therapies, and implementation of new therapies. The extant treatment system will be considered first so that the context of discovery, development, and implementation of new pharmacotherapies can be better understood.

19.2 TREATMENT STATISTICS

The Treatment Episode Data Set (TEDS) is another SAMHSA [24] data set that summarizes patient demographics and treatment characteristics of the 1.9 million patients admitted to treatment centers that report to individual state administrative systems. This system is not comprehensive but captures data that can be analyzed for year-to-year changes as well as long-term treatment trends.

As can be seen in Table 19.1, heroin admissions in the TEDS system increased from 1992 to 2002. In fact, heroin admissions accounted for 15% of the treatment admissions, making it the largest illicit drug for which individuals seek treatment. Admissions for adolescent heroin use tripled in the 1990s (TEDS 2000 data not shown). Male heroin users outnumber female users. A plurality of heroin users are white. Subtle shifts in racial composition of patients entering treatment and route of administration differences were also seen. The number of white heroin admissions increased from 1992, whereas the number of African-Americans had a slight drop (data not shown). Moreover, the data show a shift toward less injection use and more inhalation use among African-Americans whereas inhalation and injection use both increased among white heroin users. Additionally, the use of methadone as a treatment in this system appears to be declining for both injectors and inhalers.

In contrast, the overwhelming majority of prescription opiate users admitted into treatment are white. They also abuse the drug by the oral route of administration. The male-to-female ratio appears to be close to 1, suggesting a greater likelihood for females to be prescription opiate abusers. Although the number of treatment admissions represents only a small percentage of the treatment admissions in TEDS, the percentage has increased from 1992 to 2002. An even smaller percentage of these patients received methadone in their treatment.

Methadone was developed by in the 1960s as a treatment for heroin addiction (for a review, see [25]). There is documented evidence that methadone reduces morbidity

TABLE 19.1 Comparison of Treatment Facilities Admissions for Heroin Users and Prescription Opiate Users in 1992 and 2002 from TEDS

Patient Demographics and Use Variables	Heroin Admissions		Prescription Opiate Dependence Admissions	
	1992	2002	1992	2002
Number of admissions	170,370	285,657	13,671	45,605
Male, %	—	69	—	54
White				
Percent	—	48	—	88

Methadone therapy, %	—	—	—	19

^aMexican and Puerto Rican admissions (excludes Cubans and other Hispanic groups).

and mortality associated with heroin addiction. The death rate falls dramatically for former heroin addicts in methadone maintenance treatment [26–28]. Methadone is primarily dispensed in specialty outpatient clinics [29]. The National Survey of Substance Abuse Treatment Services reported that 1215 of 13,428 facilities dispensed methadone or levomethadyl acetate (LAAM). On the survey reference date of October 1, 2000, 17% of the patients in the survey were reported to be in methadone treatment. There are a number of barriers to obtaining methadone. Patients entering treatment for detoxification from heroin actually receive methadone less often than patients receiving longer treatment (22 vs. 35%) [29]. For prescription opiate-dependent patients entered into the 2000 TEDS data set, those who worked full or parttime were more likely to receive methadone. No sex differences in receipt of methadone were seen in the TEDS system for prescription opiate users. Other potential barriers are lack of treatment facilities in rural areas. For example, admission rates for prescription opiate user treatment increased 155% in the United

States. The greatest increase (269%) was seen in nonmetropolitan areas (without a city population of 10,000 or more).

19.3 CURRENT TREATMENT NEEDS

To address the unmet treatment needs of heroin- and prescription opiate-dependent patients, several changes are needed. The first is a greater test of the concept of medical maintenance with methadone. Initial studies have shown that medical maintenance is not only feasible but can be highly successful with stable patients [30–33]. Expanded research with methadone in this model is necessary to continue the medicalization of the treatment of opiate dependence. Increasing access to the medical care system should have benefits to patients accessing medical care [34].

The second change needed is a greater uptake of opiate pharmacotherapy with buprenorphine (SUBUTEX) and buprenorphine/naloxone (SUBOXONE).

19.4 BUPRENORPHINE STUDIES

19.4.1 Buprenorphine and Buprenorphine/Naloxone: Studies for Food and Drug Administration Approval

Buprenorphine was recognized to possess pharmacological properties that could be utilized for treatment of opiate dependence [35]. Specifically, buprenorphine had an ability to block the effects of administered morphine while it had intrinsic opiatelike effects that would likely ensure better compliance than a nonopiate or narcotic antagonist. Its duration of action implied that it could be administered as a single daily dose. Buprenorphine was classified as a partial agonist of the μ receptor [36]. Its partial agonist properties produce a ceiling effect on respiration [37] that suggests a lower risk of severe respiratory depression or apnea. Moreover, the withdrawal syndrome reported was minimal [35].

Buprenorphine's efficacy was established in three large, prospective studies that formed the basis of its marketing approval. Johnson et al. [38] reported the initial efficacy of buprenorphine in the outpatient setting. In this study, the 8-mg sublingual buprenorphine liquid-per-day group had better retention and lower opiate use than an active control group receiving 20 mg of oral methadone. A second study reported that an 8-mg dose of sublingual buprenorphine liquid produced better retention and less opiate use than a 1-mg buprenorphine active-control group [39].

During the development of buprenorphine, Reckitt-Benckiser decided to market a solid dosage form of different tablet strengths. Moreover, it also agreed with National Institute on Drug Abuse (NIDA) that a second dosage form that contained naloxone would serve as an abuse deterrent. The two decisions to develop solid dosage forms of different tablet strengths and to add naloxone as an abuse deterrent necessitated additional research in the following areas: dosage form development, determination of the ratio of buprenorphine to naloxone, efficacy and safety of the tablet formulations, and bioequivalence of buprenorphine tablets to sublingual liquid. Dosage strengths of 2 and 8 mg were chosen. Several clinical pharmacology

studies were conducted in various opiate-dependent populations maintained on morphine [40, 41], methadone [42], or buprenorphine [43] to determine the ratio of buprenorphine to naloxone for the combination tablets. A 4:1 buprenorphine–naloxone ratio was chosen. A randomized, double-blind, placebo-controlled multicenter trial compared the buprenorphine tablet, the buprenorphine–naloxone tablet, and placebo in opiate-dependent patients [44]. Both tablets reduced opiate use in the first month of the study compared to placebo.

The U.S. Food and Drug Administration (FDA) approved buprenorphine (SUBUTEX) and buprenorphine/naloxone (SUBOXONE) in October 2002. These medications are indicated for the management of opiate dependence. As there are other medications used in the management of opiate dependence, the comparative efficacy of buprenorphine will be reviewed before addressing the implementation issues.

19.4.2 Buprenorphine: Comparative Efficacy Studies

The Cochrane Review Group recently reviewed the efficacy of buprenorphine versus placebo or methadone [45]. Thirteen studies were reviewed. Buprenorphine was judged to be superior to placebo in terms of retention at all buprenorphine doses, but high and very high doses were needed to show greater suppression of heroin abuse than placebo. In comparison to methadone, buprenorphine does not retain patients as well as methadone and does not suppress heroin use as well as methadone. Study design issues may confound the conclusion of inferior suppression of heroin use of buprenorphine. For example, there are two randomized, active controlled studies that allow flexible dosing with buprenorphine and methadone. Mattick et al. [46] randomized 405 opiate-dependent patients in three methadone clinics to buprenorphine or methadone in a flexible dosing design. There were no differences in illicit opiate use across groups, although retention in the buprenorphine group (50%) was less than that seen in the methadone group (59%, *n.s.*). Johnson et al. [47] randomized 220 patients to one of four medications groups: buprenorphine (16–32 mg), methadone low dose (20 mg), methadone high dose (60–100 mg), or levomethadyl acetate (75–115 mg). There were no differences in illicit opiate use in the buprenorphine versus methadone groups. The buprenorphine-treated group had a nonstatistically significantly lower retention (58%) than the high-dose methadone group (73%).

Gowing et al. [48] have recently reviewed the efficacy of buprenorphine for the management of opiate withdrawal. Buprenorphine was compared to methadone (three studies), clonidine (seven studies), or differing rates of dose tapering of buprenorphine. Buprenorphine-treated patients completed treatment more often than clonidine patients and with fewer adverse effects. No differences in completion rate were seen between buprenorphine and methadone, although buprenorphine may provide better symptom management. Gradual dose reduction of buprenorphine may assist patients in completing withdrawal. A recent study evaluated two dose regimens of buprenorphine tablets (2–4–8–4–2 or 8–8–8–4–2 mg/day) versus clonidine in the management of heroin withdrawal [49]. Both dose regimens suppressed withdrawal better than clonidine, but the high-dose buprenorphine group was superior to clonidine on such measures as drug craving.

19.4.3 Buprenorphine: Implementation Issues and Pilot Studies

While the final stages of development of the buprenorphine products were ongoing, the U.S. Congress passed the Drug Abuse Treatment Act (DATA) of 2000. This law allows qualified physicians to prescribe FDA-approved opiate products in Schedules III–V of the Controlled Substances Act (CSA) that are indicated for the treatment of opiate dependence. Both products were scheduled into C. III of the CSA. Qualified physicians can prescribe these products (as defined in the DATA) to 30 opiate-dependent patients in their medical practices. Physicians can be qualified by experience or training. Then they request a waiver to prescribe buprenorphine. To date, over 7000 physicians have received waivers.

Physicians in office-based practice can now prescribe buprenorphine. A consensus statement on office-based treatment of opiate dependence using buprenorphine has now been developed [50]. O'Connor et al. [51] reported that patients randomized to buprenorphine in a primary-care setting had greater retention and less opiate use than those randomized to a methadone clinic. Fiellin et al. [52] treated heroin-dependent patients with thrice-weekly buprenorphine in a primary-care center. Eleven of the 13 patients were retained through the 13-week study period. Nine of the 13 patients achieved at least 3 consecutive weeks of opiate-free urines. Gibson et al. [53] reported that retention and reduction of opiate use were equivalent in patients assigned to buprenorphine in a specialty clinic versus a primary-care setting.

Additional research on buprenorphine products has been conducted. The NIDA's Clinical Trials Network has conducted medically assisted withdrawal studies in clinic settings [54]. In this report, 234 buprenorphine/naloxone-treated patients were followed for 13 days; 68% completed the detoxification. Only 1 of 18 serious adverse events was considered possibly related to buprenorphine. The authors concluded that the use of buprenorphine/naloxone in diverse community settings was practical and safe. Lintzeris et al. [55] reported on an Australian study of the implementation of buprenorphine in community treatment settings by general practitioners and pharmacists. Patients were randomized to either buprenorphine or methadone in this study. Seventy-four percent of the methadone transfer and 46% of the heroin patients treated with buprenorphine were retained for six months in treatment. The authors concluded that buprenorphine could be safely delivered in the community setting.

19.5 FUTURE CHALLENGES FOR OPIATE DEPENDENCE TREATMENT

The NIDA will concentrate on the development of non-opiate-based treatments for opiate dependence. Naltrexone is approved for the prevention of relapse in formerly opiate-dependent patients. Although naltrexone has been shown to be superior to placebo for prevention of relapse in a criminal justice population [56], the major problem with naltrexone is adherence to therapy. One of the naltrexone depot dosage forms has been tested in an outpatient trial [57]. A clinical trial of a depot form of naltrexone in outpatients being treated for alcoholism was recently published [58]. It is anticipated that the development of this dosage form will continue. If and when the depot form of naltrexone is marketed for alcoholism, studies will commence in detoxified formerly opiate-dependent populations. Since adherence is the major problem with the use of naltrexone, it is anticipated that this dosage form would be an advance in treatment.

The management of opiate withdrawal by nonopioid medications is another medications development challenge. For example, lofexidine is a congener of the α_2 agonist clonidine. It has been tested in opiate-dependent populations undergoing withdrawal. The initial double-blind, placebo-controlled multicenter trial of lofexidine was halted due to overwhelming efficacy. Although buprenorphine has been shown to be superior to clonidine, the potential of a medication like lofexidine would be for managing withdrawal in settings where buprenorphine and methadone were not available.

Buspirone has been shown in an initial study to reduce opiate withdrawal symptomatology in patients undergoing detoxification from heroin or medically assisted withdrawal from methadone [59].

19.6 DRUG DISCOVERY EFFORTS FOR OPIATE DEPENDENCE TREATMENTS

The potential success in developing new treatments for opiate dependence will depend on translation of neuroscience-based treatments into new medications. Two of the most promising targets will be highlighted here. One of the most promising therapeutic targets is a corticotropin releasing factor (CRF) receptor antagonist. CRF has been shown to be involved in the mediation of responses involving arousal, affect, and aversion to negative situations (for a review, see [60]). CRF is involved in coordinating responses to internal or external threats to an organism's homeostasis. Drug withdrawal syndromes can be considered an aversive state. Writhing, chewing movements, "wet dog" shakes, salivation, lacrimation, diarrhea, and increased emotionality characterize opiate withdrawal in rats. The CRF-1 antagonist CP-154,526 has been shown to attenuate several signs of naltrexone-precipitated withdrawal in opiate-dependent rats [61]. The CRF-1 antagonist CRA 1000 attenuated naloxone-precipitated withdrawal signs in chronically morphine-treated mice [62]. The CRF-1 antagonist antalarmin reversed naloxone-induced place aversion in morphine-pelleted rats [63]. Lu et al. [64, 65] have reported a role for CRF in morphine relapse in animal models. These investigators reported that CP-154,526 blocked the reinstatement of footshock-induced morphine place preference. Shaham et al. [66] reported that CRF reinstated heroin self-administration and α -helical CRF blocked footshock-induced reinstatement of heroin self-administration. CP-154,526 also attenuated footshock-induced reinstatement of heroin self-administration in rats [67]. The aggregate results suggest that a CRF antagonist would attenuate opiate withdrawal and block conditioned aversion responses and stress-related lapses or relapses to opiates.

The cannabinoid antagonist SR141716A (rimonabant) has also shown promise as a potential medication for the treatment of opiate dependence in preclinical models. Rimonabant has been shown to decrease components of the opiate withdrawal syndrome in rats [68]. Rimonabant blocked morphine-induced place preference in mice [69]. In rats trained to self-administer heroin, rimonabant reduced self-administration in fixed-ratio [69] and fixed- and progressive-ratio conditions [70, 71]. Further, Devries et al. [71] showed rimonabant blockade of heroin-seeking behavior that was provoked by either a priming injection of heroin or heroin-associated cues. These data provide a strong rationale for testing of rimonabant in opiate-dependent patients. For further details, the reader is referred to LeFoll and Goldberg [72].

19.7 SUMMARY AND CONCLUSIONS

Abuse and dependence on opiate drugs are chronic problems. There have been some fundamental changes in abuse patterns in the United States, notably the increase in both heroin use and prescription opiate abuse in the last 10 years. The increase in heroin use has been fueled by the availability of concentrated heroin that can be used for inhalation or smoking. Adolescent heroin use has risen concomitantly with the higher concentration of heroin. The age of first heroin use has dropped by nine years, suggesting that a greater number of young people will become heroin dependent. Treatment for heroin abuse is currently the primary diagnosis of individuals treated for illicit drug use in the TEDS database. The incidence figures noted in adolescents suggest that it will remain so for some time.

An increase in prescription opiate use and treatment for opiate abuse have been recorded in the drug use and treatment system databases. There are more prescription opiate users than heroin users (and more women than men are prescription opiate users who seek treatment). This is reflected in the fact that more opiate users than heroin users reported getting treatment for their dependence [73]. A different locus of use has been noted for prescription opiate users; that is, the greatest increase has been in rural areas.

Consequently, the treatment delivery system for opiate users is undergoing some unique challenges. Even in light of a worsening situation, funding for pharmacotherapy seems to be diminishing in the publicly funded part of the treatment system. This situation needs to be reversed. Additionally, treatment delivery must be given in reasonable proximity to the users' domiciles. This means that the treatment system must undergo a major change to reach the prescription opiate users who are concentrated in rural areas. The current availability of SUBUTEX and SUBOXONE should help to address the problem of treatment delivery outside urban areas by qualified physicians who can now prescribe these medications as part of their primary-care practices. Physicians are currently constrained to a 30-patient limit. This limit can be changed by legislation or administrative action at the level of the secretary of the U.S. Department of Health and Human Services (DHHS).

The use of methadone for "office-based practice" would be another useful tool for physicians to be able to prescribe for patients. This has been evaluated in several studies and is a feasible treatment approach.

The development and marketing of new medications, primarily nonopiate in nature, are feasible, although the time frame is several years away. Multiple medications of diverse mechanisms might be used as stand-alone medications or as combinations. For example, the testing of a CB-1 antagonist or inverse agonist would be a high priority for testing. Nonopiate medications with good efficacy would usher in another change to the management of opiate dependence. Moreover, these medications would likely enjoy broad societal support.

20.1 INTRODUCTION

Pain remains a prominent factor in all facets of medicine. Pain helps maintain the safety and integrity of subjects by alerting them to potential injury. Pathways that transmit nociceptive stimuli from the periphery to the central nervous system have been studied extensively. However, situations exist where survival may depend upon minimizing or ignoring pain. A major function of the sensory nervous system is its ability to filter sensory input. The vast array of sensation from all modalities makes it essential for the individual to focus upon a selected few and to place others in the background. Thus, it is not surprising that the nervous system has developed a highly complex system to “filter,” or modulate, the perception of pain.

Pain is unlike most sensations. The International Association for the Study of Pain defines pain as “an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage” [1]. Thus, in addition to the actual perception of the stimulus, pain requires a processing of this input to provoke a sensation that is perceived as unpleasant. This contrasts with traditional sensations that are more easily quantified, such as touch and

temperature. What makes the understanding of pain particularly difficult is that stimuli that are considered painful in one situation may not be perceived as painful in a different context. Many of us have found bruises after playing a sport without remembering when the injury occurred. Yet, at other times, a less intense injury may be associated with profound pain. The ability to dissociate the stimulus from pain has been observed in patients on opioids, which diminish pain without interfering with more basic sensations. Indeed, patients on opioids may comment, "The pain is still there but it doesn't hurt." Another complexity in understanding pain is its many different types, as illustrated by the wide range of descriptors, such as sharp, dull, aching, shooting, throbbing, and burning.

Clinically, pain has been categorized as somatic, visceral, and neuropathic [1a]. Somatic, or "nociceptive," pain is typically a result of tissue injury. It is common, easily recognized by most people, and typically described as sharp or aching. Of the various types of pain, this is the most sensitive to opioids and the simplest to treat. Visceral pain, as its name implies, involves internal organs. The nature of the pain is dependent upon the structure involved and can feel like cramping, or pressure, such as cholecystitis, pancreatitis, or angina. It can be referred to a different region of the body, such as the shoulder pain seen with diaphragmatic irritation.

Neuropathic pain, on the other hand, is quite novel and unique. It is the most atypical pain and the most difficult to treat. It is usually associated with injury to peripheral nerves, as seen in plexopathies or neuropathies, central pain pathways, as in thalamic pain syndromes, or combinations of both. The pain is typically described as burning, dysesthetic, or shooting, and patients commonly have difficulty describing it. A number of syndromes such as reflex sympathetic dystrophy and causalgia (complex regional pain syndromes) are due to involvement of the sympathetic nervous system. Although traditional analgesics, including the opioids, are used to treat this pain, they often require far higher doses than normal, which in turn can lead to increased side effects and difficulties with the patients tolerating them. Many other classes of drugs are used to manage neuropathic pain, including antidepressants and anticonvulsants. Unfortunately, it is not unusual for these drugs, either alone or in combination, to give only partial relief.

In addition to its quality, pain is also characterized by its duration as either acute or chronic. Once a pain has been present for six months, it is typically considered chronic [1a]. Clinically, acute and chronic pain can be separated by more than their duration. Acute pain is often associated with autonomic effects, such as tachycardia, papillary dilation, and diaphoresis, signs typically associated with pain. However, most of the autonomic signs seen acutely are lost in chronic-pain states, making it more difficult for the clinician to assess the severity of the pain. Indeed, with chronic pain the clinician is left with only the assessment by the patient. Chronic pain is further complicated by a number of factors and can be very difficult to treat. These include sensitization and "wind-up" and the commonly associated depression seen in these patients. Other issues, such as the impact of potential disability and financial issues, also can complicate its diagnosis and treatment.

Thus, pain is not simple. It requires higher integrative processing to define its unpleasant aspects and its perception is highly dependent upon the situation in which it occurs and its meaning. There are three major types of pain that differ in their sensitivities to pharmacological approaches, and most clinical pain is composed of combinations of them.

20.2 PAIN PATHWAYS

Pain pathways are complex. They involve far more than the simple conduction of an impulse from a peripheral nociceptor to the brain. Ascending systems dissociate discriminative aspects of pain from the emotional components (Table 20.1) while descending pathways provide a mechanism for the modulation of nociceptive transmission at all levels of the neuroaxis. Discriminative aspects of pain have been well localized to specific pathways and regions of sensory cortex. In contrast, the affective component is mediated predominantly through subcortical pathways involving limbic circuits, making their mapping difficult.

Nociceptors have a widespread localization peripherally in skin and subcutaneous tissues, joints, muscles, blood vessels, and viscera and are located on neurons whose cell bodies are within the dorsal root or trigeminal ganglia [1a–4]. Myelinated nociceptors respond to either intense mechanical or mechanothermal stimuli whereas unmyelinated nociceptors are polymodal, responding to thermal, mechanical, or chemical stimuli. Certain unmyelinated nociceptors are particularly sensitive to pH and chemical agents, such as histamine and bradykinin, which are released by tissue damage and can be further sensitized by serotonin and prostaglandins in the damaged tissues.

Aδ fibers and C fibers carry pain information from the periphery to the central nervous system. Aδ fibers are myelinated and thicker than the unmyelinated C fibers, explaining their faster transmission of pain impulses (5–30 m/s when compared to C fibers (0.5–2 m/s) and contributing to the phenomenon of “first” and “second” pain.

The primary sensory neuron cell bodies are located in the dorsal root ganglia or cranial nerve ganglia. Axons from dorsal root ganglia enter the spinal cord through the dorsal horn where they ascend or descend for several spinal cord segments before interacting with intrinsic spinal cord neurons. Aδ fibers typically terminate within lamina I (marginal zone) and, to a lesser extent, within lamina V. C fibers tend to

TABLE 20.1 Comparison of Neospinothalamic and Paleospinothalamic Pain Pathways

	Neospinothalamic Tract	Paleospinothalamic Tract
Anatomy		
Thalamic target	VPL	Intralaminar and midline nuclei
Intermediate synapses between dorsal horn and thalamus	None	Periaqueductal gray, reticular formation
Thalamic projections	Somatosensory cortex (parietal lobe)	Subcortical (cingulate gyrus, limbic system, hypothalamus)
Pain sensation	Fast or first pain Discriminative component (intensity, localization, quality) Well localized	Slow or second pain Affective component (“hurt”) Poorly localized
Other sensations	Light touch, temperature	

Note: Sensory neurons with their cell bodies in the dorsal root ganglia enter the dorsal horn of the spinal cord where the Aδ fibers synapse in laminae I and V and ascend to the thalamus as the neospinothalamic tract and the C fibers synapse primarily in laminae I and II and ascend as the paleospinothalamic, or spinoreticular, tract.

project to lamina I and lamina II (substantia gelatinosa) where they synapse with interneurons and neurons that project rostrally. Some axons synapse on motor neurons in the ventral horn, completing the pain reflex arc. Trigeminal ganglia axons enter the brain stem and project to the spinal nucleus of the trigeminal tract, which is analogous to the substantia gelatinosa within the spinal cord (Fig. 20.1b).

Nociception is transmitted rostrally through two important pathways: the lateral spinothalamic tract (Fig. 20.1, Table 20.1) and the anterior spinothalamic tract. The lateral spinothalamic tract receives information regarding the location and intensity of the nociceptive stimuli and has a distinct somatotopic organization within the tract as it ascends and comprises the neospinothalamic pathway. Axons in the tract cross to the opposite side of the spinal cord over several spinal segments through the anterior commissure and proceed to ascend to the ventroposterior lateral (VPL) nucleus of the thalamus. Axons in the trigeminal thalamic tract cross the midline and synapse in the ventroposterior medial (VPM) nucleus of the thalamus. From the thalamus, these tracts ascend to primary somatosensory cortex with its well-defined somatotopic organization. Cortical lesions, such as seen in strokes, lead to loss of this well-localized pain sensation. This pathway transmits primarily nociception carried by A δ fibers and corresponds to first pain, in distinction from second pain, which involves primarily C fibers and the paleospinothalamic tract.

The anterior spinothalamic, which is a component of the paleospinothalamic tract (Fig. 20.2), is involved with the affective, or unpleasant, component of pain. It carries “second” or “slow” pain and it is this component of pain that is sensitive to opioids. Unlike the neospinothalamic tract which ascends directly to the thalamus, the paleospinothalamic tract has numerous interactions with a range of brain stem nuclei (nucleus gigantocellularis and parabrachial region), the reticular formation, and periaqueductal gray before converging on the medial and intralaminar nuclei of the thalamus. From there, the impulses are relayed not to the somatosensory cortex but to limbic structures and association cortex instead, including the anterior cingulate gyrus, amygdala, and hypothalamus. The importance of many of these higher structures in pain clinically has now been supported by positron emission tomography [5, 6]. Nociception carried by this pathway is slower, due to both the slower conduction rate of the C fibers and the multiple synapses within the pathway as it ascends, leading to the description of this pain as second or slow pain. Unlike the rapidly conducted first pain, second pain is poorly localized and more diffuse with a dysethetic quality. The selectivity of opioids for this pathway may help explain the observation by some patients after taking opioids that they can still feel the pain, but it does not bother them, consistent with a selectivity of the opioid response to the affective component of pain, or “hurt,” carried by the paleospinothalamic tract.

20.3 DESCENDING PAIN MODULATORY PATHWAYS

The central nervous system can modulate the perception of pain. This can be observed in a variety of situations, such as athletes who are unaware of an injury until after the game or the lower morphine requirements of wounded soldiers during the stress of battle [7]. Even acupuncture has been proposed to involve the activation of intrinsic antinociceptive pathways [8]. In the 1960s, Wall and Melzack proposed

Figure 20.1 Ascending spinothalamic tract. Major pathways for pain (and temperature) sensation. (a) Spinothalamic system. (b) Trigeminal pain and temperature system, which carries information about these sensations from the face. (Reproduced with permission from D. Purves et al. (2001). *NeuroScience*. Sinauer, Sunderland, MA, Fig. 10.3.) (See color insert.)

the “gate control” theory, which has now been much expanded, to explain how central systems can modulate peripheral nociceptive input [9]. Descending pathways from the brain that are heavily influenced by opioids and a number of other selected neurotransmitters are primarily responsible for these actions (Fig. 20.3) [2, 10–12].

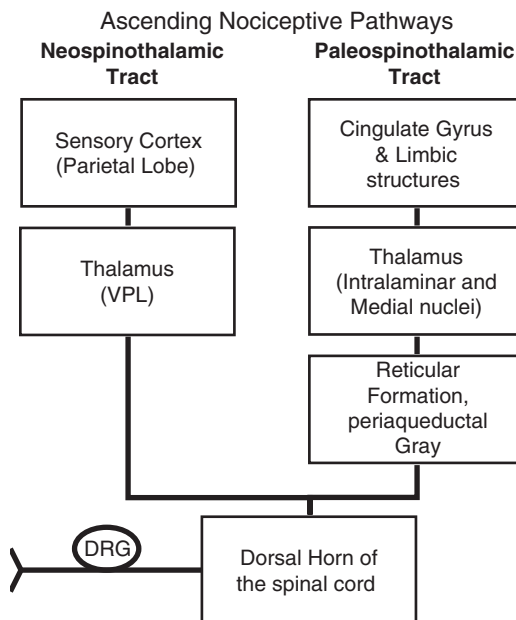

Figure 20.2 Ascending nociceptive pathways.

Pain sensation is modulated by the descending pain modulatory pathways in a balance of excitation and inhibition [2, 3, 13, 14]. The periaqueductal gray (PAG) is particularly important in this system. Early studies showed that morphine was an extremely potent analgesic when microinjected into this site [15]. Additional studies have identified a number of midbrain areas, including the locus ceruleus, nucleus raphe magnus, and nucleus paragigantocellularis [11, 16–18]. Stimulation of the PAG produced analgesia in rodents that was naloxone reversible [19–21], observations similar to those seen clinically [22]. These studies imply that activation of the PAG would produce an opioidlike analgesia. The PAG receives input from a wide range of structures, including the amygdala, frontal and insular cortex, and hypothalamus. It projects to the nucleus raphe magnus, which then descends to suppress pain transmission in the dorsal horn of the spinal cord. The PAG receives input from a wide range of structures, including the somatosensory cortex, frontal and insular cortex, amygdala, and hypothalamus. The PAG, in turn, projects to neurons in the nucleus raphe magnus and other nuclei in the rostral ventral medulla, the nucleus reticularis paragigantocellularis in particular [6–9]. The medullary nuclei transmit signals in the dorsolateral column down to the same regions of the dorsal horn of the spinal cord in which primary sensory neurons synapse onto secondary sensory neurons. Descending axons from the PAG, raphe nuclei, and locus ceruleus also project directly to the spinal cord.

20.4 NEUROPHARMACOLOGY OF PAIN

Many neurotransmitter systems have been implicated in both the transmission of nociception and its modulation. Indeed, few transmitters are not involved. Some

Figure 20.3 Descending pain modulatory pathways. The descending systems that modulate the transmission of ascending pain signals. These modulatory systems originate in the somatic sensory cortex, the hypothalamus, the periaqueductal gray matter of the midbrain, the raphe nuclei, and other nuclei of the rostral ventral medulla. Complex modulatory effects occur at each of these sites, as well as in the dorsal horn. (Reproduced with permission from D. Purues et al. (2001). *NeuroScience*. Sinauer, Sunderland, MA, Fig. 10.5). (See color insert.)

provide potent pain relief, such as the endogenous opioids [1a], nicotinic analogs [23], and cannabinoids [24, 25], while others demonstrate limited activity due to ceiling effects or are restricted to specific pain syndromes. One of the best examples of agents with ceiling effects are the nonsteroidal anti-inflammatory drugs, which are quite

effective for mild/moderate pain but lack the efficacy needed for severe pain. Antidepressants and anticonvulsants are typically used for neuropathic pain, such as the peripheral neuropathies and postherpetic neuralgia, or headaches. Trigeminal neuralgia with its lancinating pain is quite unique and the first-line drug to treat this relatively common disorder is the anticonvulsant carbamazepine. Thus, from the clinical perspective, a wide range of drugs are valuable in pain management, with various types of pain responding differently to these agents [1a, 3, 26–28].

The most effective clinical agents in pain management remain the opioids. These drugs mimic the actions of the endogenous opioid peptides and have been classified by their selectivity for the three major classes of receptors: μ , δ , and κ . Although some agents with κ actions are available clinically, most opioid analgesics are morphine-like and are selective for μ -opioid receptors. Extensive structure–activity studies have dissected the structure of morphine and generated a host of drugs with widely dissimilar structures that act through μ receptors (Fig. 20.4). Although δ compounds are effective in animal pain models, none have yet been approved for general clinical use. There are three major families of endogenous opioids, each with its own precursor peptide: enkephalins, dynorphin A, and β -endorphin [29, 30]. The enkephalins and dynorphin A are the endogenous ligands for the δ and κ_1 receptors, respectively. The endogenous ligand for the μ receptors is still uncertain. There is evidence implicating endomorphin 1 and endomorphin 2 as well as β -endorphin, but some questions still remain. The complexity of the μ -opioid system is further illustrated by the recent identification of a number of splice variants of the cloned μ -opioid receptor MOR-1 with their distinct regional distributions and pharmacological properties [31–36]. The question that now arises is whether or not the identification of these splice variants of MOR-1 will enable the dissociation of analgesia from its troublesome side effects.

As the number of neurotransmitters involved with pain pathways has expanded, they have raised the possibility of novel approaches toward pain management [37]. Many peptidergic systems were considered “anti-opioid,” including cholecystokinin (CCK), neuropeptide FF (NPFF), and melanocyte-inhibiting factor (MIF)-related peptides, although their actions are complex and can inhibit or enhance nociceptive perceptions depending upon the situation [38]. The antio-pioid activity of CCK appears to involve activation of CCK_B receptors, while stimulation of CCK_A receptors can induce an opioid-like activity. The major focus of CCK has been on its modulation of opioid tolerance [39, 40], but this approach has not proven successful clinically. The role of substance P and calcitonin gene-related peptide (CGRP) in nociceptive transmission in the spinal cord has been well established. Opioids inhibit their release at the spinal level and antagonists looked promising in animal models. Yet, substance P antagonists have not proven themselves clinically [41].

More traditional neurotransmitter systems implicated in pain mechanisms that may be of therapeutic importance include the monoamines, acetylcholine, glutamate, glycine, and both sodium and calcium channels. Almost all the monoamines can be implicated in pain modulation, perhaps explaining the importance of many of the antidepressants in pain management. Both muscarinic and nicotinic acetylcholine systems influence pain. Many of the antidepressants used clinically are effective muscarinic antagonists, which may help explain a portion of their utility. A highly potent nicotinic acetylcholine receptor agonists has been developed [23], but its side effects were too problematic for generalized use.

Figure 20.4 Structures of selected opioids.

Glutamate has a special place in pain pharmacology [42–44]. Although *N*-methyl-D-aspartate (NMDA) receptors are involved in the production of opioid tolerance, their role in central sensitization and wind-up may be more important. These systems lead to the facilitation of the transmission of pain impulses and may play a role in the development of chronic pain states, which can be very difficult to treat. This has led some clinicians to use “preemptive analgesia” to prevent sensitization. Unfortunately, the side-effect profile of NMDA antagonists is problematic, making the use of these agents clinically unacceptable with the exception of memantine.

20.5 LOCALIZATION OF DRUG ACTION

Peripheral mechanisms associated with pain have been extensively explored. Local anesthetics, which block sodium channels, effectively prevent pain [4], but they suffer from their lack of selectivity in that they also block other sensory modalities, such as light touch. A variety of transmitter receptors located on peripheral nerves also can modulate pain transmission. For example, opiate receptors have now been identified on sensory dorsal root ganglion neurons both in the periphery and presynaptically in the dorsal horn of the spinal cord [45–49]. Opioids traditionally were thought to act centrally by presynaptic inhibition of the release of nociceptive transmitters, such as substance P or CGRP, as well as on intrinsic spinal neurons. One of the MOR-1 variants, MOR-1C, is colocalized presynaptically on neurons containing CGRP while the predominant MOR-1 is not [51]. The release of CGRP can be blocked by morphine, presumably through these MOR-1C receptors. Substance P neurons terminating within the dorsal horn do appear to be associated with MOR-1 [51]. Opioids inhibit the release of substance P, diminishing nociceptive transmission [52]. Substance P drugs also can modulate pain perception at the spinal cord level, but their utility clinically is not clear [41, 53].

Opioid receptors have been demonstrated on peripheral nerves, explaining the analgesic actions of opioids administered locally to the nerves and without central activity [54–60]. Similarly, other drugs acting through various neurotransmitter systems also can directly influence peripheral nerves, including the antidepressant amitriptyline, the NMDA antagonist ketamine, and a variety of channel blockers, as well as through central sites of action [60].

Within the brain the sites involved with nociception include a broad range of structures, particularly regions within the brain stem and limbic systems. Our understanding of the regions involved initially came from classical studies examining the sensitivity of various brain structures to the microinjection of opioids [15]. The primary sites implicated in morphine analgesia included the PAG, the nucleus raphe magnus, and the locus ceruleus, regions subsequently shown to contain high densities of opioid receptors both autoradiographically [61–64] and immunohistochemically and at the messenger RNA (mRNA) levels [65–67].

Chronic pain is pharmacologically distinct from acute pain and involves plasticity with neurochemical changes. The maintenance of chronic pain has been associated with activation of glutamate receptors. NMDA mechanisms act centrally in sensitization and are involved with plasticity. Indeed, the identification of NMDA receptors in “windup” or central sensitization [68, 69] has led to the concept that early and aggressive treatment of pain can help minimize the sensitization process [70].

20.6 ANATOMICAL DRUG INTERACTIONS AND PAIN

Pain pathways have an additional complexity. For example, morphine is a potent analgesic when administered either supraspinally or spinally in the rat. However, administering morphine to both sites simultaneously leads to a profound potentiation of their actions (i.e., synergy) (Table 20.2) [71]. The total dose of morphine required for an analgesic response when it is given both spinally and supraspinally is

TABLE 20.2 Spinal–Supraspinal Morphine Interactions

Site of Drug Administration	Morphine ED ₅₀ (μg)
Supraspinal	10 (7.23–14.17) i.c.v.
Spinal	4.2 (3.1–5.4) i.t.
Combination ^a (supraspinal–spinal)	0.7 (0.38–1.08) (0.35 i.c.v. + 0.35 i.t.)

Note: ED₅₀ = median effective dose; i.c.v. = intracerebrovascular; i.t. = intrathecal.

^aThis value corresponds to the ED₅₀ for the total dose for the animal using a supraspinal–spinal ratio of 1:1. Thus, the ED₅₀ for the combination corresponds to 0.35 μg given in each location. From [71].

at least sixfold lower than if it is given to either location alone. Thus, there are important interactions among the sites along the pain modulatory pathways.

Since then, other examples of site–site synergy have been observed. Morphine is an active analgesic when administered into the PAG, rostroventral medulla (RVM), or locus ceruleus. However, coadministration of low morphine doses which are inactive alone into combinations of these three regions elicits dramatic analgesic responses, implying the existence of synergy. The most effective combination is the PAG–RVM, whereas the PAG–LC and RVM–LC combinations are much less efficacious. Thus, there are important brain stem interactions involved with morphine analgesia.

Peripherally acting opiates also synergize with central sites. Topical morphine is effective in traditional analgesic paradigms in mice and rats [54, 58, 59, 72–74]. Under conditions that are associated with no appreciable systemic absorption, a variety of opioids produce reproducible dose–response relationships and show the same pharmacological characteristics as seen centrally. However, the combination of topical and spinal morphine is highly synergistic (Fig. 20.5). Thus, morphine shows interactions among a wide range of sites within the central and peripheral nervous systems, adding to the complexity of the system.

These interactions among sites help explain some clinical observations. Epidural opiates are widely used in pain management. The advantage is that there are far fewer side effects, such as nausea, constipation, and respiratory depression, and the drugs can give prolonged pain relief. When given epidurally, morphine concentrations in the cerebrospinal fluid at the spinal level reach levels far beyond those achieved following systemic administration. Equally important, there also is significant systemic absorption through Batson's plexus, leading to blood levels not far below those seen following intramuscular administration. Studies in animals have shown that very low morphine concentrations at the spinal level can markedly potentiate systemic morphine (Table 20.3). Intrathecal doses of morphine that are approximately 10-fold below the ED₅₀ of spinal morphine can shift the systemic morphine dose response curve sixfold to the left. Thus, the utility of epidural morphine likely reflects the combined actions of spinal and systemic drug. Since the side effects associated with morphine, such as sedation, nausea, and respiratory depression, are mediated supraspinally, side effects are avoided by the low levels of systemic drug.

The importance of peripheral sites of action have also been established in other situations. When morphine is given centrally into the lateral ventricle, one would

Figure 20.5 Interactions between topical and spinal morphine. Groups of mice ($n<10$) received topical morphine (15 mM, 2min) alone or with spinal (100 ng, i.t.). The spinal morphine dose alone had no observable analgesic action. After 30 min, when the response to topical drug alone was lost, the responses of the combinations were significantly greater ($p<0.002$). From [59].

TABLE 20.3 Peripheral–Central Morphine Interactions

Route of Administration	ED ₅₀	Shift
Spinal (i.t.) alone	305 ng, i.t.	
Systemic alone	3.1 mg/kg, s.c.	
+ 25 ng, i.t.	0.5 mg/kg, s.c.	6
+ 50 ng, i.t.	0.3 mg/kg, s.c.	10
+ 200 ng, i.t.	0.04 mg/kg, s.c.	84

Mice received various doses of morphine intrathecally to determine the ED₅₀. Additional groups of mice then received the stated fixed dose of intrathecal morphine and various doses of morphine [subcutaneous (s.c.)]. The ED₅₀ for the systemic morphine was then determined. From [54].

have assumed that its actions were restricted to the brain. However, morphine given intrathecally is rapidly secreted from the brain into the periphery by mechanisms involving P glycoprotein and can be detected in the blood [75]. These systemic levels of morphine are relevant, since a topical antagonist limited to the periphery shifts the analgesic response of supraspinal morphine over fourfold, implying that the overall response reflected interactions between central and peripheral sites. Downregulation of P glycoprotein using either an antisense or a knockout approach eliminates the ability of the topical antagonist to shift the supraspinal analgesic response, consistent with the role of P glycoprotein in transporting the drug to the systemic circulation. Thus, site–site interactions are extremely important in understanding the activity of analgesic drugs.

Interactions have also been seen among different groups of drugs working through different mechanisms. This is best illustrated by the interactions between local anesthetics and opioids at the spinal level [76] and peripherally [77, 78]. Similar

interactions topically have been observed with combinations of antidepressants, NMDA antagonists, and other classes of drugs [60].

20.7 CONCLUSION

The pathways transmitting nociceptive stimuli and those involved with its modulation are exceedingly complex. Interactions between these counteracting systems occur at multiple levels of the neuraxis, with each influencing the others. While the anatomy of the pathways has been known for many years, understanding their functional and pharmacological significance is more recent. These pathways are not static “transmission lines.” Rather, they are interacting pathways providing complex pharmacological interactions that may prove helpful in our continuing efforts in pain management.

21.1 CLONING OF VANILLOID RECEPTOR

Hot chili peppers have been long used in food, and people know well that the peppers produce a burning sensation in the mouth. The structure of capsaicin, a main pungent ingredient of capsicum peppers, was solved as 8-methyl-*N*-vanillyl-6-nonenamide in 1928 [1], and several decades later Hungarian researchers revealed that capsaicin could cause pain and desensitize further capsaicin challenge at the same time in rats [2, 3]. Three important findings—(1) that capsaicin and resiniferatoxin (RTX), a pungent substance derived from *Euphorbia* species, share a similar structure, including a vanilloid motif necessary for pungency (Fig. 21.1) [4]; (2) specific bindings of [³H]RTX to the small-diameter sensory neurons [5]; and (3) development of a competitive antagonist of vanilloid action, capsazepine (Fig. 21.1) [6]—resulted in the belief that a receptor protein was responsible for the capsaicin action. Data obtained using electrophysiological methods provided further evidence that vanilloid receptor activation allows cation influx through its ionic pore, leading to the depolarization of the nociceptive neurons, followed by action potential generation. This seems to be one of the mechanisms whereby noxious stimuli are

renamed TRPV1 as the first member of the TRPV (vanilloid) subfamily. A prototypical member of the TRP superfamily of ion channels was reported in 1989 and found to be deficient in a *Drosophila* mutant exhibiting abnormal responsiveness to continuous light [9]. Now, this large TRP superfamily of ion channels is divided into seven subfamilies (TRPC, TRPV, TRPM, TRPP, TRPN, TRPA, and TRPML) [10].

21.2 TRPV1 EXHIBITS HIGHLY SPECIFIC EXPRESSION PATTERN

TRPV1 expression at both messenger RNA (mRNA) and protein levels was extensively examined, and those studies revealed that TRPV1 is highly expressed in dorsal root, trigeminal, and nodose ganglia, specifically within a subset of small- to medium-diameter sensory neurons that project to the superficial layers of the spinal cord (laminae I and II), trigeminal nucleus, and solitary tract nucleus, respectively [8, 11–14]. These observations, plus the fact that the TRPV1 protein is detected in nerve terminals of the bladder [14], indicates that TRPV1 is expressed in both central and peripheral termini of sensory neurons involved in nociception. This expression pattern is consistent with the finding that capsaicin selectively activates unmyelinated C fibers and thinly myelinated A δ fibers. Although TRPV1 expression is also reported in a number of other neuronal and nonneuronal tissues such as brain, keratinocytes, and urinary epithelial cells [15–17] where nonnociceptive functions are hypothesized, expression level in sensory neurons appears to be much higher than in any other region. Primary afferent nociceptors have been histochemically divided into two distinct classes in the adult rodent: one expresses neuropeptides such as SP and CGRP; the other expresses specific enzyme markers such as fluoride-resistant acid phosphatase and binds the isolectin By (IBy) [18]. These two classes of neurons are sensitive to the neurotrophic nerve growth factor (NGF) and glial cell line–derived neurotrophic factor (GDNF), respectively. Both subpopulations of sensory neurons respond to capsaicin, and colocalization studies of TRPV1 with IB4 and SP probes revealed that many SP immunoreactive cells or IB4-positive cells costained with TRPV1, although $\sim 10\%$ of the TRPV1-positive neurons did not stain with either SP or IB4 [14].

It has been reported that inflammation or tissue injury induced an increase in the number of unmyelinated C fibers expressing TRPV1 [19]. Furthermore, increased TRPV1 expression induced by inflammation was predominantly observed in myelinated A δ fibers compared to C fibers [20]. NGF induced increase of TRPV1 mRNA and release of CGRP with capsaicin treatment in primary cultured DRG neurons [21]. Activation of p38MAPK (mitogen-activated protein kinase) by NGF was found to enhance the translocation of TRPV1 proteins from cell bodies in DRG to sensory nerve endings [22]. Furthermore, p38MAPK inhibitor reduced inflammatory hyperalgesia. Thus, increase of TRPV1 expression in the sensory nerve endings seems to be involved in the development of hyperalgesia.

In the visceral organs, including intestine, TRPV1 was found to be expressed throughout the sensory neurons, and most apparent expression was observed in nerve fibers that innervated the myenteric plexus of visceral organs [23]. TRPV1-expressing neurons detected with specific anti-TRPV1 antibody seem to be not vagal afferent fibers but spinal in origin.

21.3 TRPV1 ACTIVATION BY CAPSAICIN, PROTONS, AND HEAT

Upon exposure to capsaicin, TRPV1 exhibits an outwardly rectifying, nonselective cation current with high Ca^{2+} permeability [8]. Upon application of capsaicin to membrane patches excised from human embryonic kidney (HEK) cells expressing TRPV1, clear single-channel openings were observed (conductance of ~ 80 pS for Na^+) (Fig. 21.2), indicating that no cytosolic second messengers are necessary for TRPV1 activation. This channel also exhibits a voltage-dependent gating property such that depolarization promotes TRPV1 activation [24]. TRPV1 expressed alone in HEK293 cells or *Xenopus* oocytes can account for the majority of the electrophysiological properties exhibited by native capsaicin receptors in sensory neurons, including ligand affinity, permeability sequence, current–voltage (I – V) relationship, conductance, and open probability at both single-channel and whole-cell levels [8, 14, 24, 25]. These results suggest either that TRPV1 can form homomultimers (probably tetramer) without other subunits or that incorporation of subunits other than TRPV1 does not influence the functional properties.

Because capsaicin and its analogs such as RTX are lipophilic, it is quite possible that they pass through the cell membrane and act on binding sites present in the intracellular surface of TRPV1. An apparent time lag between capsaicin uptake and pungent sensation might be partially explained by such a process. Comparison of rat TRPV1 with its avian ortholog from chicken sensory neurons, which is insensitive to capsaicin, together with mutational analysis revealed that tyrosine 511 and serine 512, located at the transition between the second intracellular loop and the third TM domain, might interact with vanilloid ligands at the intracellular face of the membrane [26].

Tissue acidification is induced in pathological conditions such as ischemia and inflammation. Such acidification exacerbates or causes pain [27, 28]. Acidification of the extracellular milieu has two primary effects on TRPV1 function [14]. First, extracellular protons increase the potency of heat or capsaicin as TRPV1 agonists, in part, by lowering the threshold for channel activation by either stimulus. Second, extracellular protons can, themselves, be viewed as agonists because further acidification (to $\text{pH} < 6.0$) leads to channel opening at room temperature. Acidic solution evoked ionic currents with a mean effective concentration (EC_{50}) of about $\text{pH} 5.4$ at room temperature when applied to outside-out but not inside-out membrane patches

Figure 21.2 Representative single-channel currents in membrane patches excised from HEK293 cells expressing TRPV1 to bath-applied capsaicin ($100\ \mu\text{M}$, inside out), protons ($\text{pH} 5.4$, outside out), or heat (44°C , inside out). Dotted lines indicate closed level. Holding potential $+40$ mV.

excised from HEK293 cells expressing TRPV1 (Fig. 21.2), suggesting that protons act on amino acids in the extracellular domain of TRPV1 having side chain pK_a values in the physiologically relevant range. Mutational analyses revealed that glutamate 600, located within a putative extracellular domain, serves as an important regulator site for proton potentiation of TRPV1 activity, whereas glutamate 648 is involved in direct proton-evoked activation of TRPV1 [29]. In sensory neurons, proton-evoked currents consist of two major components: one is rapidly inactivating and Na^+ selective with a linear $I-V$ relation [30]; the other is a more sustained, nonselective cation conductance with an outwardly rectifying $I-V$ profile [31]. The latter is believed to underlie the prolonged sensation of pain, and TRPV1 may represent a responsible molecular entity for this component. In addition to its activating or modulating effects on TRPV1, protons were found to permeate the nonselective TRPV1 pore in acidic extracellular solution, resulting in marked intracellular acidification [32].

The burning quality of capsaicin-induced pain suggests that capsaicin and heat may evoke painful responses through a common molecular pathway. TRPV1 was, in fact, found to be activated by heat at $>43^\circ C$ (Fig. 21.3), a temperature threshold

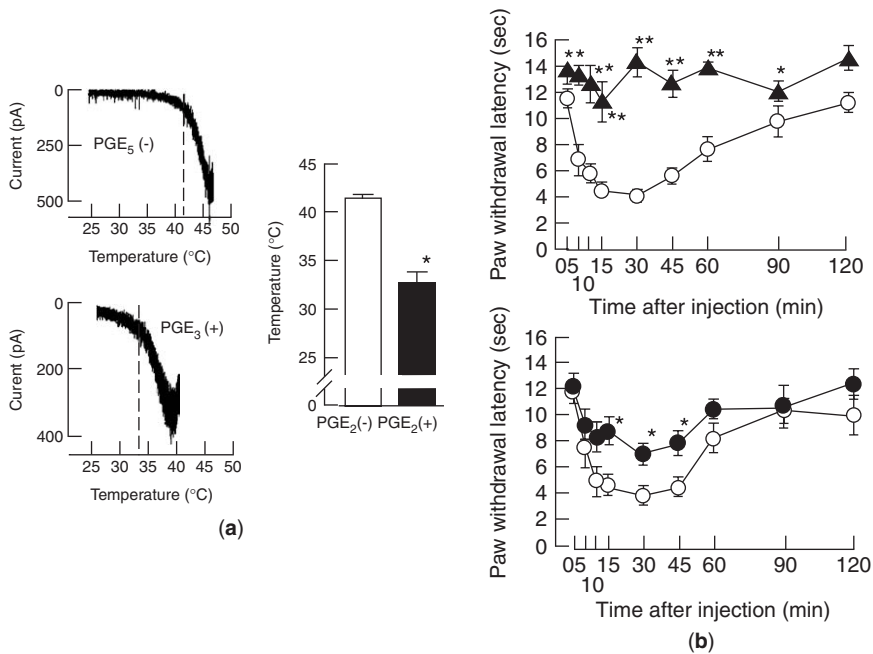

Figure 21.3 Reduction of temperature threshold for TRPV1 activation with PGE_2 ($1\mu M$), and inhibition of PGE_2 -induced thermal hyperalgesia in TRPV1- or EP_1 -deficient mice. (a) Representative temperature response profiles in the absence (upper) and presence (lower) of PGE_2 (left). Temperature threshold for TRPV1 activation in the presence of PGE_2 ($30.6 \pm 1.1^\circ C$) was significantly lower than that in the absence of PGE_2 ($40.7 \pm 0.3^\circ C$) (right). (*) $p < 0.05$ vs. $PGE_2 (-)$. (b) Paw withdrawal latency after injection of PGE_2 into hind paw in wild-type mice (open circle), TRPV1-deficient mice (closed triangle), or EP_1 -deficient mice (closed circle). (*) $p < 0.05$ and (**) $p < 0.01$ vs. wild-type mice. (From Moriyama et al., *Mol. Pain* 1: 3, 2005).

that is similar to that at which heat evokes pain *in vivo*, suggesting that TRPV1 is involved in the detection of painful heat by primary sensory neurons [14]. Heat-evoked TRPV1 currents show properties similar to those of capsaicin-evoked currents. However, there are several differences in the properties, including cationic permeability ratio and Ca^{2+} -independent desensitization, suggesting that TRPV1-mediated responses to capsaicin and heat involve distinct but overlapping mechanisms. Heat-evoked single-channel openings were observed in inside-out membrane patches excised from HEK293 cells expressing TRPV1 (Fig. 21.2), suggesting that TRPV1 is, itself, a heat sensor.

21.4 DIVERSE CHEMICAL ACTIVATORS OF TRPV1

Not only capsaicin and RTX but also other chemically related substances such as zingerol and piperin, chemicals responsible for the pungency of ginger and black pepper, respectively, were reported to have the ability to activate TRPV1 [33]. In addition to these vanilloid compounds, allicin, the chemical causing pungency in garlic, was found to activate TRPV1 [34].

Numerous endogenous lipid metabolites of arachidonic acid (AA) in plasma membrane are also capable of activating TRPV1. Palmitoyl ethanolamide (anandamide) (Fig. 21.1), an endocannabinoid, is the first such substance in lipids which might work as an endogenous ligand for TRPV1 [35]. However, anandamide's ability to be a physiologically relevant activator of TRPV1 is controversial because concentrations at which anandamide can activate TRPV1 (micromolars) are higher than those that activate G-protein-coupled cannabinoid CB_1 or CB_2 receptors (nanomolars) and because anandamide exhibits partial agonism [36]. Various oxygenated AA derivatives, including 12- and 15-hydroperoxyeicosatetraenoic acid (12-HPETE and 15-HPETE, respectively) (Fig. 21.1) were also found to activate TRPV1 [37]. These AA metabolites can be produced by lipoxygenases that introduce molecular oxygen in AA released from the membrane by phospholipase A_2 enzymes. Again, reported EC_{50} values for activation of TRPV1 by 12-HPETE or 15-HPETE are relatively high (micromolars), although, to date, no pharmacological study has been performed to examine how much 12-HPETE or 15-HPETE is produced in pathological conditions. However, Shin et al. provided evidence that 12-HPETE is produced endogenously in sensory neurons upon stimulation of sensory nerve endings by the inflammatory mediator bradykinin and activates TRPV1 [38]. This suggests that lipoxygenase products might be important in the development of inflammatory pain. *N*-Arachidonoyl dopamine (NADA) (Fig. 21.1), originally characterized in the striatum, is a full agonist of TRPV1 and the most potent endogenous lipid ligand discovered to date [39]. *N*-Oleoidopamine also possesses the ability to activate TRPV1 with the same potency as NADA [40]. However, the distribution of NADA in dorsal root ganglia (DRG) is much lower than in brain regions (striatum, hippocampus, and cerebellum). In addition, as yet, no TRPV1-mediated physiological or pathological conditions have been attributed to endogenously formed NADA, making the concept that NADA can produce pain *in vivo* obscure. On the other hand, widespread distribution of the compounds, not only in peripheral tissues innervated by TRPV1-expressing afferents, but also in the spinal cord and brain, might explain why TRPV1 is expressed throughout the central

nervous system, albeit at levels lower than in nociceptive neurons. To qualify as an endogenous activator of TRPV1, the three classes of lipids described above have to be formed by cells and be released in an activity-dependent manner in sufficient amounts to evoke a TRPV1-mediated response. Further experiments should be done to clarify the importance of the lipids.

21.5 ANTAGONISTS OF TRPV1 AND THEIR IMPLICATION IN CLINICAL SETTINGS

The two antagonists that have been traditionally used to block capsaicin receptors are capsazepine and ruthenium red. Capsazepine shares structure similarity with vanilloid compounds (Fig. 21.1). *In vitro*, capsazepine competitively antagonizes both vanilloid activation of TRPV1-mediated currents and RTX binding to membranes containing native or recombinant TRPV1. This compound can also block the activation of TRPV1 by protons, anandamide, or heat. However, there are significant species differences in the potency of capsazepine at blocking TRPV1 responses evoked by nonvanilloid stimuli. Furthermore, capsazepine is known to act on other targets, including nicotinic acetylcholine receptors at micromolar concentrations. Capsazepine was reported to inhibit some pain-related behaviors in animal models, although no clinical trials have been carried out partly because of its nonspecificity. Ruthenium red is a highly charged organic cation that acts as a noncompetitive TRPV1 antagonist, apparently by blocking the channel pore. This compound, however, is even more promiscuous than capsazepine, as it blocks a number of nonselective cation channels.

Halogenated vanilloids such as iodinated resiniferatoxin (I-RTX) and N-(3-methoxyphenyl)-4-chlorocinnamide (SB36679) seem to exhibit somewhat better selectivity [41, 42]. However, they have not been employed with much success *in vivo*. One of the surprising findings arising from the *in vivo* studies of the TRPV1 antagonists is that some of the antagonists, such as N-(4-tertiarybutylphenyl)-4-(3-chlorophenyl)-1,2,3,4-tetrahydropyrazine-1(2H)-carboxamide (BCTC) and capsazepine, were also effective for mechanical hyperalgesia in a neuropathic pain model [43, 44]. These findings apparently contradict the previous results that normal mechanical nociception was observed in mice lacking TRPV1 and that TRPV1 in a heterologous expression system did not show mechanical sensitivity [45]. The possibility that TRPV1 is involved in mechanosensation in nociceptors, especially in pathological conditions, cannot be excluded. Indeed, mechanical responsiveness in the urinary bladder appears to be diminished in mice lacking TRPV1, and proteinase-activated receptor 2 (PAR 2) agonist-induced mechanical allodynia was significantly reduced in TRPV1-deficient mice. Highly selective TRPV1 antagonists will hopefully be identified through high-throughput screening in the near future, and studies using the new selective TRPV1 antagonists will address the issue of mechanosensitivity of TRPV1.

21.6 SENSITIZATION OF TRPV1

Inflammatory pain is initiated by tissue damage/inflammation and is characterized by hypersensitivity both at the site of damage and in adjacent tissue. Stimuli that normally would not produce pain do so (allodynia), while previously noxious stimuli

evoke even greater pain responses (hyperalgesia). One mechanism underlying these phenomena is the sensitization of ion channels such as TRPV1. Sensitization is triggered by extracellular inflammatory mediators that are released *in vivo* from surrounding damaged or inflamed tissues and from nociceptive neurons themselves (i.e., neurogenic inflammation) [46, 47]. Mediators known to cause sensitization include prostaglandins, adenosine, serotonin, bradykinin, and adenosine triphosphate (ATP) [48]. Tissue acidification is also induced in the context of inflammation as described above. Among the inflammatory mediators, extracellular ATP, bradykinin, prostaglandin E₂, prostaglandin I₂, trypsin, and tryptase have been reported to potentiate TRPV1 responses through metabotropic ATP receptor (P2Y)₂, B2, EP₁, IP, and proteinase-activated receptor 2 (PAR2) receptors, respectively, in a protein kinase C (PKC)-dependent manner in both heterologous expression systems and native DRG neurons [49–53]. In addition to potentiating capsaicin- or proton-evoked currents, those mediators also lower the temperature threshold for heat activation of TRPV1 to as low as 30 °C (Fig. 21.3), such that normally nonpainful thermal stimuli (i.e., normal body temperature) are capable of activating TRPV1, thereby leading to the sensation of pain. Under these circumstances, they thus can be viewed as direct activators of TRPV1. This represents a novel mechanism through which the large amounts of mediators released from different cells in inflammation might trigger a sensation of pain. The inflammatory mediator-induced TRPV1-mediated hypersensitivity has been confirmed at the whole-animal level using TRPV1-deficient mice or mice lacking the receptors of the mediators (Fig. 21.3). PKC-dependent phosphorylation of TRPV1 has been reported to be involved in the sensitization of TRPV1 by the mediators, based on the observation that several different PKC inhibitors blocked the inflammatory mediator-induced potentiation or sensitization of TRPV1 activity. Indeed, two serine residues in the cytoplasmic domain of TRPV1 were identified as substrates for PKC-dependent phosphorylation [54, 55]. There has been extensive work demonstrating the activation of a protein kinase A (PKA)-dependent pathway that influences capsaicin- or heat-mediated actions in rat sensory neurons [56–60] as well as interactions between cloned TRPV1 and PKA [61–64]. These results suggest that PKA plays a pivotal role in the development of hyperalgesia and inflammation and that a PKA-dependent pathway is also involved in TRPV1 sensitization, and PKA-dependent phosphorylation of serine residues on TRPV1, S144, S370, and S502 has been reported [64]. Further, both PKA- and PKC-dependent pathways have been reported to function on some ligands, such as serotonin and prostaglandins [50, 65]. The physiological relevance of the two different pathways downstream of serotonin or prostaglandin exposure remains to be elucidated. The fact that only PKC activation leads to the reduction of temperature threshold for TRPV1 activation might be pertinent to this issue [50]. Disruption of interaction between phosphatidylinositol-4,5-bisphosphate (PIP₂) and TRPV1 has also been reported to be involved in the sensitization of TRPV1 downstream of phospholipase C (PLC) activation by, for example, bradykinin or NGF since the amount of PIP₂, a tonic inhibitor of TRPV1, is reduced in its hydrolysis to inositol 1,4,5-trisphosphate (IP₃) and diacyl glycerol (DAG) [66, 67]. It is also known that phospholipase A₂ (PLA₂) is activated downstream of PLC activation, leading to the generation of lipoxygenase products such as 12-HPETE from AA [38]. These facts indicate three different pathways can work to modulate TRPV1 function downstream of PLC activation: a PKC-dependent pathway, a

PIP₂-mediated pathway, and a lipoxygenase product-mediated pathway. It is not currently clear which pathway is predominantly functioning in vivo.

In addition to the direct activation of TRPV1, acidification induced in inflammation also shifts the temperature response curve of TRPV1 to the left so that the channel can be activated at lower temperatures (lower than body temperature) and responses to heat are bigger at a given suprathreshold temperature. This phenomenon might also contribute to inflammatory pain. Calmodulin kinase II (CaMKII) was also reported to control TRPV1 activity upon phosphorylation of TRPV1 at S502 and T704 by regulating capsaicin binding [68]. Thus, phosphorylation of TRPV1 by several different kinases seems to control TRPV1 activity through the dynamic balance between phosphorylation and dephosphorylation. Furthermore, NGF activates the phosphatidylinositol 3-kinase (PI3K) and extracellular signal-regulated protein kinase (ERK), and then PI3K and ERK have been reported to sensitize TRPV1 [69]. Mechanisms underlying TRPV1 sensitization seem to be very complicated.

21.7 DESENSITIZATION OF TRPV1

Capsaicin not only causes pain but also seems to exhibit analgesic properties, particularly when used to treat pain associated with diabetic neuropathies or rheumatoid arthritis [7]. This paradoxical effect may relate to the ability of capsaicin to desensitize nociceptive terminals to capsaicin as well as to other noxious stimuli following prolonged exposure. At the molecular level, an extracellular Ca²⁺-dependent reduction of TRPV1 responsiveness upon continuous vanilloid exposure (electrophysiological desensitization) may partially underlie this phenomenon [7, 8], although physical damage to the nerve terminal and depletion of SP and CGRP probably contribute to this effect as well. Ca²⁺- and voltage-dependent desensitization of capsaicin-activated currents has also been observed in rat DRG neurons [70–73]. This inactivation of nociceptive neurons by capsaicin has generated extensive research on the possible therapeutic effectiveness of capsaicin as a clinical analgesic tool [74, 75].

Desensitization to capsaicin is a complex process with varying kinetic components: a fast component that appears to depend on Ca²⁺ influx through TRPV1 [70–73] and a slow component that does not. Calcineurin inhibitors reduce TRPV1 desensitization (the slow component), indicating the involvement of the Ca²⁺-dependent phosphorylation/dephosphorylation process [73]. In agreement with this finding, phosphorylation of TRPV1 by CaMKII was reported to prevent its desensitization [68]. In addition, PKA-dependent phosphorylation of TRPV1 has been reported to mediate the slow component of TRPV1 desensitization [61]. TRPV1 becomes dephosphorylated upon exposure to capsaicin and this phosphorylation can be restored by 8bromo-cyclic adenosine monophosphate (cAMP).

CaM has also been reported to be involved in Ca²⁺-dependent desensitization of TRPV1. CaM was found to bind to the carboxyl terminus of TRPV1. Disruption of the CaM binding segment prevented extracellular Ca²⁺-dependent TRPV1 desensitization to brief capsaicin application, although some desensitization was still observed upon more prolonged capsaicin application in cells expressing the mutant [76]. It has also been reported that CaM binds to the first ankyrin repeat in the amino terminus of TRPV1 and to be involved in desensitization [77]. Whether the amino or carboxyl terminus is more predominantly involved in Ca²⁺-dependent desensitization

by CaM is not known. Ca^{2+} -dependent desensitization is a relatively common feature of many cation channels, including cyclic nucleotide-gated channels [78], L-type Ca^{2+} channels [79, 80], P/Q-type Ca^{2+} channels [81], N-methyl-D-aspartate (NMDA) receptor channels [82, 83], and TRP channels [84, 85]. It may represent a physiological safety mechanism against a harmful Ca^{2+} overload in the cell, especially during large Ca^{2+} influx through the channels.

21.8 KNOCKOUT MOUSE STUDY

Electrophysiological analysis in a heterologous expression system revealed the importance of TRPV1 in detecting noxious thermal and chemical stimuli. To determine whether TRPV1 really contributes to the detection of these noxious stimuli in vivo, mice lacking this protein were generated and analyzed for nociceptive function [45, 86]. Sensory neurons from mice lacking TRPV1 were deficient in their responses to each of the reported noxious stimuli: capsaicin, proton, and heat. Consistent with this observation, behavioral responses to capsaicin were absent and responses to acute thermal stimuli were diminished in these mice. Pungency-related behaviors were not observed in the TRPV1-deficient mice when capsaicin was applied to their oral cavity, suggesting the involvement of TRPV1 in detection of pungency. In contrast, TRPV1 knockout mice showed normal physiological and behavioral responses to noxious mechanical stimuli, implying the existence of other mechanisms for the detection of such stimuli. The most prominent feature of the knockout mouse thermosensory phenotype was a virtual absence of thermal hypersensitivity in the setting of inflammation. These findings indicate that TRPV1 is essential for selective modalities of pain sensation and for tissue injury-induced thermal hyperalgesia.

The extent to which TRPV1 underlies the responses to noxious thermal stimuli and the contribution of other heat-sensitive channels remain to be clarified. There was a drastic reduction of heat sensitivity in DRG neurons cultured from TRPV1-deficient mice, but a small yet significant percentage of DRG neurons showed large heat-evoked current responses to heat stimuli over 55 °C. Furthermore, the TRPV1-deficient mice showed impaired responses to noxious thermal stimuli only over 50 °C, and a small but significant amount of heat-evoked *c-fos* induction persisted in spinal cord laminae I and II of TRPV1-deficient mice. These data supported the idea that other heat-sensitive channels contribute to the transmission and perception of high-intensity noxious thermal stimuli.

Recent studies have provided further support for TRPV1 involvement in inflammatory pain and have, in addition, demonstrated that the participation of TRPV1 in pain sensation may also extend to neuropathic pain, mechanical allodynia, and mechanical hyperalgesia. These conclusions are based on enhanced expression of TRPV1 in sensory neurons in the context of these conditions as well as behavioral effects of TRPV1 antagonism with capsazepine [22, 43, 49, 87, 88]

21.9 OTHER TRPV CHANNELS INVOLVED IN NOCICEPTION

TRPV2 (VRL-1) might be a potential candidate for the receptor detecting the high heat stimulus responsible for the residual high temperature-evoked nociceptive

responses observed in TRPV1-deficient mice. TRPV2 with about 50% identity to TRPV1 was found to be activated by high temperatures with a threshold of $\sim 52^{\circ}\text{C}$ [89]. TRPV2 currents showed similar properties to those of TRPV1 such as an outwardly rectifying I - V relationship, inhibition by ruthenium red, and relatively high Ca^{2+} permeability. Intense TRPV2 immunoreactivity was observed in medium- to large-diameter cells in rat DRG neurons [89–92]. In addition, many of the TRPV2-positive neurons costained with the anti-neurofilament antibody N52, a marker for myelinated neurons. Temperatures activating TRPV2 are more harmful to our body than those activating TRPV1. Therefore, expression of TRPV2 in the myelinated sensory fibers seems reasonable because A δ fibers can transmit the nociceptive information much faster than C fibers. A δ mechano- and heat-sensitive (AMH) neurons in monkey are medium- to large-diameter, lightly myelinated neurons that fall into two groups: type I AMHs have a heat threshold of $\sim 53^{\circ}\text{C}$, and type II AMHs are activated at 43°C [93]. TRPV2 expression might account for the high thermal threshold ascribed to type I AMH nociceptors. However, it has very recently been reported that nociceptors lacking TRPV1 and TRPV2 still have normal heat responses [94]. This result suggests the existence of another heat-sensitive mechanism.

Two TRPV channels, TRPV3 and TRPV4, have been found to be activated by warm temperatures, ~ 34 – 38°C for TRPV3 and ~ 27 – 35°C for TRPV4, in heterologous expression systems and to be expressed in multiple tissues, including, among others, sensory and hypothalamic neurons and keratinocytes [95–99]. TRPV4 was originally reported as an osmotically activated channel (VROAC or OTRPC4 from vanilloid receptor-related osmotically activated channel or OSM-9-like TRP channel 4, respectively) [100, 101]. Several approaches, including the knockdown of TRPV4 with gene disruption or antisense oligonucleotides, have led to reports that this protein is involved in mechanical stimulus- and hypotonicity-induced nociception in rodents [102–104]. It remains unclear whether TRPV3 is involved in nociception. However, the data that TRPV1 and TRPV3 were predicted to reside on the same chromosome and that TRPV3 was sensitized upon repeated noxious heat stimuli suggest the involvement of TRPV3 in nociception.

22.1 INTRODUCTION

The use of opium, a product of the poppy plant, goes back thousands of years. The major analgesic components of opium are morphine and codeine, which are present in relatively high concentrations. Thebaine is another important compound present in opium. Although it is not active, it is widely used to synthesize a number of clinically important opioid analgesics. Following the isolation and purification of morphine and codeine, medicinal chemists synthesized thousands of analogs in an effort to avoid the side effects, which include sedation, respiratory depression, constipation, and abuse potential. Although they were not able to dissociate these actions, they did establish rigid structure–activity relationships for these drugs which, in turn, led to the proposal of distinct binding sites, or receptors, years before they were demonstrated experimentally in 1973 [1–3]. These binding sites were restricted

to nervous tissue and were highly selective for morphine and morphine-like agents. Since then, we have extended our understanding of these receptors and their endogenous ligands and have identified three classes of opioid receptors [4].

22.2 ENDOGENOUS OPIOIDS

The demonstration of opioid receptors quickly led a number of investigators to look for their endogenous ligands, eventually leading to the isolation and identification of a series of opioid peptides (Table 22.1) [5–10]. They fall into three families based upon their precursor peptides and the selectivity for the members of the opioid receptor classes. Each opioid peptide family is generated from a distinct precursor peptide encoded by three different genes. Yet, all the active opioid peptides contain the sequence Tyr–Gly–Gly–Phe–Leu or Tyr–Gly–Gly–Phe–Met as their first five amino acids. The only exception are the endomorphins (Table 22.1). These peptides, which have been isolated from brain [11], are highly μ selective. However, it is not clear whether they are synthesized de novo or generated from a precursor.

22.2.1 Enkephalins

The enkephalins were the first opioid peptides identified, and they played a major role in establishing the explosion within the field of neuropeptides. The enkephalins consist of a pair of pentapeptides that share the same first four amino acids, differing at the fifth with either a methionine (Met⁵-enkephalin) or a leucine (Leu⁵-enkephalin). They have distinct regional distributions within the brain and are the endogenous ligands for the δ receptors (see below).

Studies of the enkephalins were initially hindered by their lability, due in large part by the actions of peptidases. The demonstration that they could be stabilized by substituting a D-amino acid at position 2 led to the generation of a host of stabilized

TABLE 22.1 Opioid and Related Peptides^a

[Leu ⁵]enkephalin	Tyr–Gly–Gly–Phe–Leu
[Met ⁵]enkephalin	Tyr–Gly–Gly–Phe–Met
Dynorphin A	Tyr–Gly–Gly–Phe–Leu –Arg–Arg–Ile–Arg–Pro–Lys–Leu–Lys–Trp–Asp–Asn–Gln
Dynorphin B	Tyr–Gly–Gly–Phe–Leu –Arg–Arg–Gln–Phe–Lys–Val–Val–Thr
α -Neoendorphin	Tyr–Gly–Gly–Phe–Leu –Arg–Lys–Tyr–Pro–Lys
β -Neoendorphin	Tyr–Gly–Gly–Phe–Leu –Arg–Lys–Tyr–Pro
β -Endorphin	Tyr–Gly–Gly–Phe–Met –Thr–Ser–Glu–Lys–Ser–Gln–Thr–Pro–Leu–Val–Thr–Leu–Phe–Lys–Asn–Ala–Ile–Ile–Lys–Asn–Ala–Tyr–Lys–Lys–Gly–Glu
Endomorphin-1	Tyr–Pro–Trp–Phe–NH ₂
Endomorphin-2	Tyr–Pro–Phe–Phe–NH ₂
Orphanin FQ/ nociceptin	Phe–Gly–Gly–Phe –Thr–Gly–Ala–Arg–Lys–Ser–Ala–Arg–Lys–Leu–Ala–Asp–Glu

^aCommon sequences are highlighted.

Figure 22.1 Schematic of opioid peptide precursors.

derivatives. Using these compounds, investigators have established that the enkephalins can produce analgesia through receptor mechanisms distinct from those of morphine.

The enkephalins are generated from a larger precursor that contains a number of copies of the enkephalins (Fig. 22.1). There are six copies of Met⁵-enkephalin and one copy of Leu⁵-enkephalin. However, several of the Met⁵-enkephalin may actually be contained in larger peptides (peptide F, the octapeptide, and the heptapeptide). It is not known if these extended peptides are active or simply are broken down to Met⁵ enkephalin. Thus, their significance remains unknown.

22.2.2 Dynorphins

There are three major peptides within this family: α -neoendorphin, dynorphin A, and dynorphin B. Each contains the sequence of Leu⁵-enkephalin as the first five amino acids. Dynorphin A is the endogenous ligand for κ receptors, specifically κ_1 . Although dynorphin B and α -neoendorphin also label κ receptors, there has been the suggestion that they may have a slightly different binding selectivity that may be due to the existence of κ receptor subtypes [12]. All three peptides also elicit analgesia through unique receptor mechanisms.

22.2.3 β -Endorphin

β -Endorphin has 31 amino acids, making it the largest of the opioid peptides. Yet, its N-terminus still contains the Met enkephalin sequence. As with dynorphin, there

originally were questions as to whether it was pharmacologically relevant or simply the precursor of Met⁵-enkephalin. That question was answered with the identification of the enkephalin precursor as well as that for β -endorphin, pro-opiomelanocortin (POMC), which also generates the important peptides adrenocorticotrophic hormone (ACTH) and melanocyte-stimulating hormones α -MSH and β -MSH. Unlike the other opioid peptides that are widely distributed within the central nervous system, POMC is synthesized within the brain only in the arcuate nucleus, further distinguishing it from the enkephalins. However, the major location of POMC and its peptides is within the pituitary, where β -endorphin has been shown to be coreleased with ACTH, an important stress hormone responsible for the release of cortisol. This association has suggested the possibility that β -endorphin may be involved with stress analgesia.

22.2.4 Orphanin FQ/Nociception

Although not formally a member of the opioid peptide family, orphanin FQ/nociception (OFQ/N) is strikingly similar in structure to dynorphin A. Like dynorphin A, OFQ/N contains 17 amino acids, but it contains phenylalanine at position 1 instead of tyrosine. OFQ/N labels the opioid receptor-like 1 (ORL1) receptor with very high affinity but does not compete opioid receptor binding. However, if ORL1 receptors are coexpressed with an opioid receptor, OFQ/N acquires the ability to compete opioid binding, presumably due to dimerization of the two receptor classes. Thus, it appears to be closely related to opioids, if not formally one.

22.3 OPIOID RECEPTORS

Opioid receptors were initially proposed based upon the structure–activity relationships of literally hundreds of morphine derivatives. Indeed, the concept of opiate receptors was well entrenched prior to their actual identification in binding assays in 1973 [1–4]. Three major families of opioid receptors were proposed from pharmacological studies and then confirmed in binding assays and then through cloning. Studies in the dog led Martin to propose μ (morphine-preferring) and κ (ketocyclazocine-preferring) receptors, which display high affinity for the dynorphins [13]. This was followed by the identification of δ receptors selective for the enkephalins [5, 14].

22.3.1 μ Receptors

Most of the analgesics that we use to treat pain are morphine-like and act, at least in part, through μ receptors. The μ receptors have a variety of actions. Of these, analgesia is the most commonly desired. Opioid analgesia is particularly intriguing since it does not interfere with primary sensations. Patients retain the ability to feel light touch, temperature, sharp/dull, and vibration, unlike therapy with local anesthetics. Instead, the opiates diminish the subjective “hurt” associated with pain, making these agents quite unique and valuable.

Continued use of morphine-like drugs leads to tolerance, which is defined as a diminished response with a continued dose of a drug or the need to increase the drug dose over time to maintain a response. With the opioids, this is easily seen for all

opioid actions, including analgesia, although the rate to which tolerance develops for each one action may vary. Dependence is also associated with μ -opioid use. Dependence is seen through the expression of withdrawal upon the abrupt discontinuation of the opioid or the administration of an opioid antagonist to a subject who has been maintained on an opioid for an extended period of time. The length of time and the dose of the drug determine the severity of the withdrawal syndrome, which in turn is an indication of the degree of dependence. It is important to distinguish between dependence and addiction. Whereas dependence is a physiological response seen in every subject receiving the drugs, addiction is a behavioral drug-seeking response which is actually quite rare when these drugs are used for legitimate medical purposes.

The μ opioids induce a variety of other actions, including sedation, respiratory depression, and inhibition of gastrointestinal transit. Although they have been used to treat diarrhea, this action is more commonly a problematic side-effect manifested as constipation, particularly in pain patients. Sedation is another sideeffect that can be limiting in the use of these agents. Indeed, morphine was named after the Morpheus, who was the god of sleep.

The μ -opiate receptor was first demonstrated biochemically in 1973 with the demonstration of highly selective opioid binding to membranes from the brain [1–3]. Since then, the receptor has been cloned [15–18] and has been identified as a member of the G-protein-coupled receptor family [19]. Like other G-protein-coupled receptors, μ -opioid receptors have seven transmembrane domains with an extracellular N-terminus and an intracellular C-terminus (Fig 22.2a). Following the binding of an opioid to the receptor, the receptor activates a G-protein which then induces a signaling cascade. Opioid receptors are typically inhibitory and act predominantly through G_i and G_o classes of G-proteins.

The concept of multiple μ -opiate receptors goes back 25 years [20] and is particularly important in understanding the clinical actions of these drugs [21, 22]. From the clinical perspective, multiple μ receptors help explain opioid rotation and the variability in responses, observations difficult to reconcile with a single μ -opioid receptor. In opioid rotation, patients highly tolerant to one μ opiate can be switched to a different μ opiate with a markedly enhanced analgesic response to the second drug [23]. This is due to incomplete cross tolerance, consistent with slight differences in the receptor mechanism actions of the two agents. In terms of the sensitivity, some patients respond far better to one μ opioid than another. Both observations can be replicated in animal models. In CXBK mice, morphine is a very weak analgesic with a potency 5- to 10-fold less sensitive than the traditional CD-1 animal. On the other hand, other μ opioids, such as methadone, fentanyl, and heroin, retain full analgesic activity in the CXBK animal, implying that their actions are distinct from those of morphine [4, 22].

The suggestion of multiple μ -opioid receptors has now been confirmed at the molecular level through the identification of a number of splice variants of the μ -opioid receptor MOR-1 in mice, rats, and humans [24–30] (Fig. 22.2b). MOR-1, the μ -opiate receptor that was cloned in 1993, has four exons. Exons 1, 2, and 3 encode the seven transmembrane domains of the receptor while exon 4 encodes the last 12 amino acids in the C-terminus. The major series of splice variants in all three species involve variants that are alternatively spliced downstream of exon 3, with a variety of different exons in place of exon 4. The differences among these variants is restricted to the tip of the C-terminus (Fig. 22.2c). Although some variants share

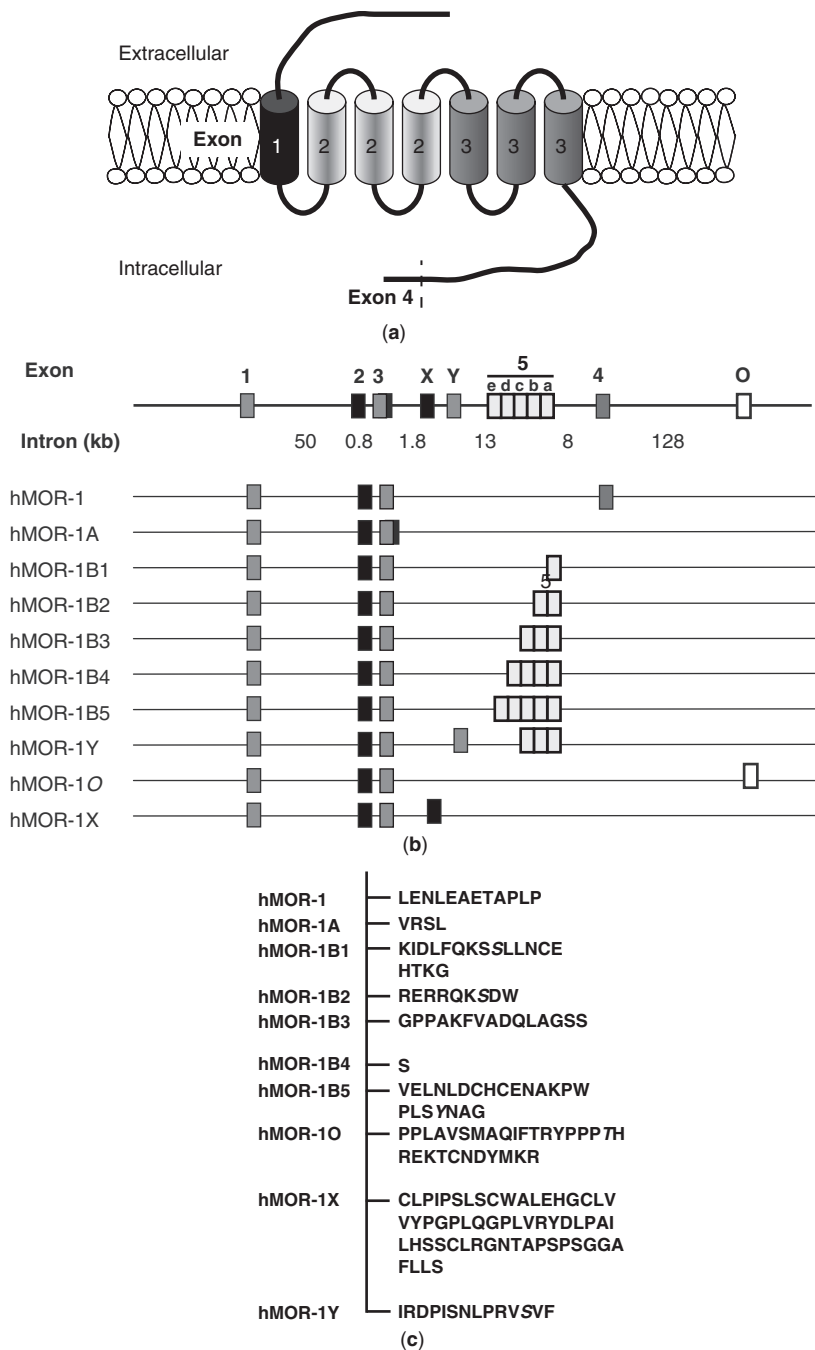

Figure 22.2 Schematic of MOR-1 (a) MOR-1 within membrane. The exons responsible for coding the different regions are indicated. (b) Alternative splicing of MOR-1 in humans. Note that only full-length variants are shown, which involve splicing at the 3' end. There is another series of 5' spliced variants. (c) Amino acid sequences of alternatively spliced C-terminus of human MOR-1 variants downstream from exon 3.

these spliced exons, all the amino acid sequences downstream of exon 3 are unique and many are identical or highly homologous among species. The binding pockets responsible for the docking of the opioid ligands within the receptor are defined by the seven transmembrane domains. Thus, all these C-terminus splice variants have identical binding pockets, explaining their similar affinities for μ opioids and their high selectivity for μ drugs. However, these changes in the C-terminus do influence the transduction systems and impact on both the efficacy and potency of drugs acting through them [24–26, 29, 31]. In mice, these C-terminus variants also have different distributions regionally and even within cells [32–35]. Furthermore, one variant, MOR-1C, is associated with calcitonin gene-related peptide (CGRP) while MOR-1 is not [32].

In mice, and possibly humans and rats, there is a second series of splice variants at the N-terminus that generate truncated proteins that lack all seven transmembrane domains seen in MOR-1 [28]. The potential pharmacological significance of these variants is not clear, but they have been demonstrated in the brain at both the messenger RNA (mRNA) and protein levels and there are indications that they may be pharmacologically irrelevant.

22.3.2 δ Receptors

The δ receptors were first proposed from studies examining the pharmacology of the enkephalins [14], which are their endogenous ligand. Since then a wide range of synthetic peptides and nonpeptides that are selective for δ receptors have been developed and widely used to characterize the actions of these receptors in animal models. However, there are not any clinically available δ ligands at present and our understanding of their actions in humans is not yet well understood.

The δ receptors are members of the G-protein-coupled receptor family and show marked homology to the μ receptor, particularly in the transmembrane domains. However, the δ receptors are unique in terms of their binding selectivity and are readily distinguished from μ receptors. They are expressed in different regions of the brain and are presumably involved in a variety of distinct physiological responses.

The δ -opioid receptor DOR-1 also has seven transmembrane domains encoded by three exons [36, 37]. Unlike MOR-1, the C-terminus of DOR-1 ends within the third coding exon and there is no C-terminus splicing. Several splice variants of DOR-1 have been reported, but they do not appear to be pharmacologically relevant [38, 39].

22.3.3 κ Receptors

The κ receptors were first proposed from the benzomorphan ketocyclazocine, but we now know that their endogenous ligand is dynorphin A. The κ ligands have been examined clinically and several are available, including pentazocine, nalorphine, and nalbuphine. These early κ drugs were mixed κ agonists– μ antagonists. Studies with more selective κ drugs have confirmed their analgesic activity, but the drugs proved problematic due to their psychotomimetic effects, actions that were also seen with the mixed agonist–antagonist drugs. The highly selective κ drugs that were in clinical trials have been withdrawn.

The κ receptors are also members of the G-protein-coupled receptor family. They were cloned soon after the δ receptors [40–42]. The cloned κ -opioid receptor KOR-1

has three coding exons that encode a seven-transmembrane receptor and the transmembrane domains have high homology with the other members of the opioid receptor family. However, its binding selectivity and distribution within the brain are distinct.

22.4 OPIOID RECEPTOR DIMERIZATION

G-protein-coupled receptors have an additional layer of complexity due to their tendency to associate with themselves (homodimers) or other G-protein-coupled receptors (heterodimers) [43, 44]. Similar observations have been made with opioid receptors [45–48]. In some cases, heterodimers take on pharmacological characteristics unlike those of either receptor expressed alone [46–48]. Thus, this ability to interact with additional receptors to generate pharmacologically unique dimers extends the number of potentially important opioid receptors manyfold. To make matters even more difficult, opioid receptors also can associate with receptors of other classes, as shown between opioid and β -adrenergic and α -adrenergic receptors [49, 50]. Thus, the presence of three opioid receptors can lead to a host of novel receptor classes due to interactions with other receptors.

22.5 ORPHANIN FQ/NOCICEPTIN AND ITS RECEPTOR

There is a fourth receptor with high homology to the traditional opioid receptors, termed ORL-1 [51–56], which is the receptor for a novel peptide termed nociceptin or orphanin FQ [57, 58]. This 17-amino-acid peptide is distinct from the opioid peptides in that its first amino acid is phenylalanine rather than tyrosine. It displays no appreciable affinity for the traditional opiate receptors. However, the high homology of the ORL-1 receptor with the opioid receptors suggests a common ancestry. Interestingly, OFQ/N is important in the modulation of pain. At low concentrations, OFQ/N is hyperalgesic and enhances pain perception, whereas higher doses are analgesic. The analgesic actions of OFQ/N are reversed by opioid antagonists, which is somewhat unexpected since OFQ/N itself does not bind to opioid receptors. However, when coexpressed, MOR-1 and ORL-1 receptors dimerize and display a unique pharmacological profile in which opioids and OFQ/N can displace each other with a high potency not seen when each receptor is displayed alone [48].

22.6 CONCLUSIONS

The opiate peptides and opiate receptors comprise a highly complex system within the central nervous system (CNS). Although intimately involved with analgesia and pain modulation, they have a host of other functions. Three classes of opioid receptors were proposed from classical pharmacological studies and each family has been cloned. Early work proposing multiple μ -opioid receptors also have been confirmed with the isolation and identification of a host of splice variants of the μ -opioid receptor MOR-1. The complexity of the opioid system is further illustrated by the tendency of opioid receptors to dimerize and associate with other opioid receptors as well as unrelated classes of G-protein-coupled receptors.

23.1 OVERVIEW

This chapter will address recent developments in the treatment of migraine. The recent promising clinical trials using a new antimigraine medication, BIBN4096BS (see Fig. 23.3 below), heralds the advent of a new generation of therapeutics. BIBN4096BS targets the receptor for the neuropeptide calcitonin gene-related peptide (CGRP), which appears to play a causal role in migraine pain. We will discuss the rationale and therapeutic implications of modulating CGRP, including its potential for acting at multiple sites in the trigeminovascular system. We will then discuss the currently used acute and preventative pharmacological treatments. Of particular interest is the increasing evidence that antiepileptic drugs may be an effective prophylactic treatment for migraine. Future strategies to selectively downregulate CGRP synthesis and the potential use of migraine drugs for other forms of trigeminal-mediated pain, such as temporomandibular disorder and trigeminal neuralgia, will be explored.

23.2 WHAT IS MIGRAINE?

Migraine is a debilitating chronic episodic disorder characterized by attacks of debilitating headaches and other associated symptoms. Migraine affects 12% of the general population at least once a year [1, 2]. It is estimated that the lifetime prevalence may be as high as 18% [3]. It is one of the most underdiagnosed and undertreated neurological diseases [4]. In this section, we will provide a brief review of the history and the now-accepted clinical diagnostic criteria of migraine.

23.2.1 Historical Perspective

People have been suffering from migraine for millennia. The first evidence of migraine is suggested by neolithic skulls from 7000 BCE that show signs of trephination, an ancient procedure that has been used to treat migraine as late as the mid-seventeenth century [5]. Descriptions of migrainelike pain have been found in Babylonian tablets dating back to 3000–4000 BC and Egyptian papyri from 1550 BC [6]. We owe to Hippocrates (c. 400 BCE) the recognition of the syndrome now known as migraine. The term *migraine* originates from the Greek word *hemicrania*, provided by Galen in the second century AD. Despite this long history, it has really only been since the 1990s that significant therapeutic inroads have been made in our understanding and treatment of migraine.

23.2.2 Definition of Migraine

The International Headache Society (IHS) developed in 1988 and reviewed in 2004 a classification system for headaches [7, 8]. But until recently these criteria have been used loosely to define migraine for research purposes. Migraines are divided in two major groups, migraines without aura and migraines with aura. Migraines without aura are defined as headaches lasting 4–72 h (untreated or unsuccessfully treated) with at least two of the following: (1) pulsating quality, (2) unilateral location, (3) moderate or severe intensity, and (4) aggravation by routine physical activity. It has been suggested by some physicians that these criteria can be remembered by the first

initial as a “puma” chewing on your brain. In addition to these core criteria, migraine also must fulfill at least one of the following two criteria: (1) nausea and/or vomiting and (2) photophobia and phonophobia. An important point for considering the mechanism behind the pain is that the untreated headache can last for days.

An aura consists in focal neurological phenomena that precede or accompany the headache. The aura can be visual, sensory, or motor and may involve language or brain stem disturbances. Migraines with aura are less common and occur in about 15% of migraineurs [3], although an estimated 30% of migraineurs experience auras at some time [9].

Migraine is a chronic condition, with episodic attacks of variable frequency, that disrupts normal daily activities and has severe economic repercussions [10–12]. Many patients rely on nonprescription medications such as aspirin, acetaminophen, and ibuprofen. However, they often are not effective when pain is moderate to severe and are commonly overused [13, 14]. This can lead to chronic headaches, or “rebound headache.” Migraines are more frequent during the most productive years of a person’s life. Based on a survey by the World Health Organization, severe migraine was rated as one of the most disabling chronic disorders [15].

There is a marked sex bias among migraineurs [1]. Migraine occurs in 18% of women, in contrast to a 6% frequency in men. In children prior to puberty, the frequency of migraine is about 6% for both boys and girls. After menopause, many, but not all, women report a decrease in migraines. One of the most common triggers of migraines is the timing during estrus cycle. While a molecular explanation for this link has not been forthcoming, several mechanisms have been proposed [16].

23.3 ROLE OF CGRP IN MIGRAINE

A causal role for CGRP during the painful phase of migraine has been a topic of speculation for the past 15 years. In this section, we will describe how CGRP fits into the currently prevailing model for migraine. We will briefly describe the synthesis and known activities of CGRP that support the hypothesis that CGRP contributes to the painful phase of migraine. We will then describe the conclusive evidence from two clinical studies showing that administration of CGRP causes a headache and that a CGRP receptor antagonist can block migraines.

23.3.1 Neurovascular Model

Migraine is now generally accepted to be a neurovascular disorder involving the meningeal and cerebral blood vessels of the cranial vasculature [17–19]. By neurovascular disorder, it is meant that dilation of blood vessels and pain are triggered by neural rather than vascular signals [20, 21]. The identity of those neural signals remains undefined. However, activation of serotonergic and noradrenergic brain stem nuclei has been detected by positron emission tomography during migraine [22, 23]. This suggests the possibility of dysfunction of the aminergic neurons of the brain stem that modulate the craniovasculature. Indeed, given the heterogeneity of migraine, it seems possible that there will be multiple mechanisms by which the pain may be triggered.

Whatever the initial trigger, it is clear that a key player in the pain pathway is the trigeminal ganglion. Nerves from the trigeminal ganglion control cerebral blood flow and provide the pain-sensitive sensory innervation of the cerebrovasculature [24–26]. The trigeminal ganglion is also the major source of CGRP innervation of craniofacial structures and the cerebrovasculature [24, 27]. The ganglion is a heterogeneous collection of neurons with CGRP in ~25% of the neurons, primarily in unmyelinated nociceptive fibers [28]. The importance of trigeminovascular CGRP is highlighted by a report that human cerebral arteries are 10 times more sensitive than coronary arteries to CGRP [29].

While the role of the trigeminal nerves in migraine is increasingly evident, the link between the initiation of migraine and the invocation of the trigeminovascular system is not known. The prevailing current theory is that migraine is initiated by a dysfunction of brain stem neurons that modulate craniovascular sensory input [17]. According to this model, this dysfunction leads to changes in meningeal blood vessel dilation and a reflexlike response of perivascular trigeminal nerves [17, 19]. A complementary model has been proposed in which a wave of cortical spreading depression leads to activation of parasympathetic and trigeminal afferents, which then causes vessel dilation and nociception [30]. Cortical spreading depression is associated with the aura that precedes some migraines [31–33]. This model does not account for migraine without aura, but the authors speculate that the aura may be subclinical. Either way, it is intriguing that a genetically engineered mouse that contains a calcium channel mutation found in familial hemiplegic migraine patients, who tend to have auras, is more susceptible to cortical spreading depression [34]. Mutations in the P/Q calcium channel and Na^+ , K^+ –adenosine triphosphatase (ATPase) have been identified in these patients [35, 36]. Whether this mouse model has elevated trigeminal activity or CGRP release remains to be seen.

The neurovascular model is consistent with clinical evidence that CGRP levels are elevated in the jugular outflow of migraineurs and decreased upon treatment with triptan antimigraine drugs, coincident with pain relief [4, 17, 37]. Activation of trigeminovascular afferents in the meninges and at the major vessels leads to release of CGRP substance P and neurokinin A. These peptides are known to cause neurogenic inflammation. Neurogenic inflammation is the “sterile” inflammatory response involving vasodilation, plasma extravasation (vessel leakage), and mast cell degranulation [38]. Neurogenic inflammation has been demonstrated upon trigeminal activation in animals, but it has not been established in migraine patients [17]. Release of CGRP and other neuropeptides at the efferent terminals in the brain stem contributes to nociception. This involves central sensitization to lower pain response thresholds and allodynia, which causes previously innocuous stimuli, such as combing of hair, to be painful [39–41]. Thus, peripheral CGRP release is believed to cause vasodilation and neurogenic inflammation and release in the brain stem helps relay nociceptive signals to the central nervous system (CNS) in migraine [42, 43].

23.3.2 CGRP Synthesis and Actions

CGRP was discovered over 20 years ago as an alternative RNA splicing product from the calcitonin gene (Fig. 23.1) [44]. CGRP is prominent in nerve fibers surrounding peripheral and cerebral blood vessels and it is the most potent peptide

Figure 23.1 Schematic of calcitonin/α-CGRP gene. (a) Alternative processing of primary transcript in thyroid C cells yields primarily calcitonin messenger RNA (mRNA), while CGRP mRNA is the primary product in neurons. The alternative polyadenylation sites following exons 4 and 6 are indicated. (b) Primary sequence of human α-CGRP peptide. The disulfide bond is indicated.

dilator known [24, 45–47]. This vasodilatory activity has been confirmed in two of three lines of CGRP knockout mice [48, 49]. Coincident with vasodilation, CGRP plays an important role in neurogenic inflammation and nociception. CGRP triggers mast cell release of proinflammatory cytokines and inflammatory agents [47]. In a study using homozygous CGRP null mutant mice, CGRP was required for somatic and visceral pain signals associated with neurogenic inflammation [50]. In addition to its actions at the afferent terminals, CGRP modulates nociceptive input via central pathways. Notably, injection of CGRP into the trigeminal nucleus of the brain stem elicits a cardiovascular response that is similar to painful stimuli [51, 52].

Consistent with these biological activities, abnormal levels of CGRP have been implicated in hypertension, migraine, subarachnoid hemorrhage, and myocardial infarction [53]. As described below, the ability of CGRP to induce headache [54] and a CGRP receptor antagonist to alleviate migraine [55] firmly establish the importance of elevated CGRP in migraine pain [42, 43, 56]. While the objective of clinical efforts has been to reduce CGRP actions, elevated CGRP can also be beneficial. For example, following myocardial infarction it is believed that elevated CGRP release plays a protective role during ischemia [57–59].

23.3.3 Multiple Sites of CGRP Action in Trigemino-vascularity

There are three potential sites of action for CGRP (Fig. 23.2). The best characterized site of CGRP action is on the vasculature. Human cerebral vessels have functional CGRP receptors and the vascular smooth muscle cells express the calcitonin

Figure 23.2 Model depicting likely sites of action of CGRP and CGRP antagonist drugs in trigeminovascularity. A pseudounipolar trigeminal ganglion neuron innervating meningeal vessels and projecting to the brain stem is depicted. (1) CGRP receptors are present on the smooth muscle and endothelium of the vasculature. (2) Receptors are present on dural mast cells that can release cytokines and inflammatory agents. (3) There are CGRP receptors on the ganglion neurons and on secondary neurons in the brain stem. The CGRP receptor is shown as a seven-pass transmembrane protein with the associated single-pass RAMP1 protein. Signals from cytokine receptors and the CGRP receptors are predicted to activate mitogen-activated protein (MAP) kinase cascades that stimulate CGRP enhancer activity. The known enhancer elements are indicated.

receptor-like receptor (CLR) and receptor activity modifying protein 1 (RAMP1) proteins that comprise the CGRP receptor [60, 61]. Inhibition of vascular CGRP receptors by the CGRP antagonist BIBN4096BS was shown to inhibit CGRP-induced dilation of the human middle cerebral and middle meningeal arteries [62]. In addition to actions on major vessels, CGRP and presumably the antagonist can also act on receptors located on pial arterioles. Dilation of these meningeal vessels and the associated neurogenic inflammation are believed to be important events in migraine.

The second potential site of CGRP action is on receptors on dural mast cells. CGRP is known to induce mast cell degranulation. Mast cells release histamine and other inflammatory agents and proinflammatory cytokines. In this capacity, the CGRP antagonist should block both meningeal vessel dilation and neurogenic inflammation.

The third potential site is on neurons. There are CGRP receptors on the primary sensory trigeminal ganglion neurons [61] and the second-order sensory neurons within trigeminal nuclei in the caudal brain stem and upper cervical spinal cord [39, 63]. CGRP binding to the ganglion neurons might potentially create a positive-feedback loop with increased CGRP synthesis and secretion. This hypothesis is currently being tested. Inhibition of these CGRP actions by the BIBN4096BS drug would likely reduce the persistent activation of the ganglion neurons. CGRP action on brain stem neurons is known to be involved in relaying nociceptive signals to the

thalamus. BIBN4096BS would likely reduce this nociceptive signaling and the sensitization of second-order neurons that is believed to contribute to migraine pain. Inhibition of the trigeminovascular system at either or both of these sites would also be expected to diminish the allodynic effects and effects from autonomic parasympathetic ganglia that are associated with migraine [40].

23.3.4 Injection of CGRP Induces Migrainelike Headaches

The possible causative role of CGRP in migraine has been studied in a double-blind crossover study. Twelve subjects, all of them migraineurs, were administered human CGRP or placebo intravenously on two different days. Two patients developed hypotension and one had an infection, and these three subjects were excluded. Eight of nine patients had immediate headache, within 40 min of the infusion of CGRP versus only one of nine treated with placebo. This immediate headache did not fulfill criteria for migraine. All nine patients had a delayed headache, from 1 to 12 h after the beginning of the infusion of CGRP versus only one receiving placebo. In three of the nine patients treated with CGRP, the delayed headache fulfilled the criteria for migraine [54].

23.3.5 Therapeutic Efficacy of CGRP Receptor Antagonist

The final proof that CGRP plays a causal role in migraine pain is the recently reported efficacy of a novel nonpeptide CGRP receptor antagonist, BIBN4096BS (Fig. 23.3) [55]. Doods and colleagues [64] identified BIBN4096BS as a potent and highly specific antagonist to human CGRP receptors (Boehringer Ingelheim) [29, 62, 64]. BIBN4096BS binds to the human CGRP receptor with over 100-fold higher affinity than the CGRP receptor in other species [29, 64]. BIBN4096BS binds the CLR/RAMP1 protein complex, and the species selectivity appears to be due to BIBN4096BS interactions with RAMP1 [65, 66].

The antagonist BIBN4096BS was shown to be effective in the acute treatment of migraine headache in an international, multicenter, randomized, double-blind European clinical trial [55]. A total of 126 migraineurs were randomized to receive BIBN4096BS or placebo. The patients treated with BIBN4096BS had both decreased headache and improvements in the associated symptoms of nausea, photophobia, phonophobia, and inability to function. The main side effect to the drug was mild

Figure 23.3 Structure of nonpeptide CGRP antagonist BIBN4096BS. BIBN4096BS, developed by Boehringer Ingelheim [64], is schematically represented (1-piperidinecarboxamide, *N*-[2-[[5-amino-1-[[4-(4-pyridinyl)-1 piperazinyl]carbonyl] pentyl] amino]-1-[(3,5-dibromo-4-hydroxyphenyl) methyl]-2-oxoethyl]-4-(1,4-dihydro-2-oxo-3(2*H*)-quinazolinyl)-, [R-(R*,S*)]-).

paresthesias that occurred in 7% of the subjects; the other side effects, nausea, headache, dry mouth, and abnormal vision, were very infrequent, 2% each. BIBN4096BS was also effective at treating CGRP-induced headache [67]. Importantly, the drug does not appear to have any adverse cardiovascular effects [68].

The significance of this proof-of-principle result is twofold. First, it presages the development of other CGRP receptor antagonists and agents that interfere with CGRP synthesis or action. Second, the CGRP antagonist is not likely to have the cardiovascular side effects of the currently used triptans.

23.4 PHARMACOLOGICAL MANAGEMENT OF MIGRAINE

The Quality Standards Subcommittee of the American Academy of Neurology developed a practice parameter for physicians in 2000, summarizing the results from evidence-based reviews on the pharmacological, including acute and preventive, as well as nonpharmacological treatments and diagnostic evaluation for migraine patients [69]. This is a very useful resource, but a review of all the drugs would be too extensive for this chapter. We will focus in the following sections on some of the most commonly used drugs included in these guidelines.

23.4.1 Acute Therapy

When a migraine attack occurs, abortive medications are used to arrest the attack or at least decrease the severity and duration of the pain and associated symptoms. An ideal abortive drug should have a rapid onset and long-lasting effect, should be easily administered, preferably orally, and should lack side effects and interactions with other medications. One must also keep in mind the cost of abortive drugs, which ranges from \$0.01/unit (generic aspirin) to approximately \$15/unit (triptans) and can be as high as \$64/unit [dihydroergotamine-45 intra muscular (DHE-45 IM)] [70].

23.4.1.1 Triptans. Perhaps the most significant advance in migraine therapy was the antimigraine drug sumatriptan in the early 1990s. Sumatriptan and the soon-to-follow related triptan drugs provide pain relief for about 60% of migraineurs within 2 h [71]. However, only about 30% of the patients were fully pain free at 2 h and only 20% were still pain free after 24 h. Thus, there is room for improved therapies.

Sumatriptan provided important clues to the underlying mechanisms of migraine pathology [17, 20, 72]. The triptans recognize the 5-hydroxytryptamine (5-HT)_{1B}, 5-HT_{1D} and 5-HT_{1F} serotonin receptors [38, 73]. At the time of the development of sumatriptan, the 5-HT₁ receptors were only known to be on blood vessels. Since then functional 5-HT_{1B}, D, F receptors have been found on perivascular trigeminal nerve terminals and the trigeminal nucleus caudalis in the brain stem [39, 74–76]. Consistent with the multiple locations of the 5-HT₁ receptors, triptans can inhibit vasodilation of intracranial vessels and inhibit CGRP release to block neurogenic inflammation and central transmission of nociceptive stimuli from trigeminal nerves [38]. The ability of triptan drugs to lower CGRP levels coincident with pain relief is consistent with the causal role of CGRP in migraine discussed in the previous section.

Triptans are also able to repress transcription of the CGRP gene in cultured trigeminal ganglion neurons [56, 77]. Transcriptional repression was seen after 2–4 h,

which is close to the estimated half-life of sumatriptan and within the 12 h required for clearance from the body, especially with the newer triptans [17, 78]. While it is risky to extrapolate from cells to people, we speculate that transcriptional repression might lower CGRP levels over the long term. This may be relevant in triptan overuse syndromes, possibly during the withdrawal headache [79, 80].

Unfortunately, the triptans are not miracle drugs. As mentioned above, about one-third of patients do not respond to triptans. In addition, there is a high recurrence rate of the headache [81]. Most importantly, there are potentially lethal side effects. The triptans can cause severe vasoconstriction of coronary arteries [82]. Because of this, triptans are contraindicated in patients with established cardiovascular disease, and they should be used cautiously in patients with cardiovascular risk factors. It is also very important to be aware of the fact that frequent use of triptans is associated with chronic headaches, which proves to be a very disabling condition with poor response to therapy [80]. There are currently seven different triptans in the market. Listed in alphabetic order these are Almotriptan, Eletriptan, Frovatriptan, Naratriptan, Rizatriptan, Sumatriptan, and Zolmitriptan. Their relative efficacies have recently been compared in a meta-analysis of 53 trials [71].

23.4.1.2 Nonsteroidal Anti-Inflammatory Drugs and Nonopiate Analgesics. The most commonly used abortive drugs are likely to be over-the-counter analgesics, nonsteroidal anti-inflammatory drugs, and combination of analgesics with caffeine. These have proven to be effective but are not free of side effects, especially gastrointestinal symptoms. Another important aspect to consider is the risk of chronic daily headaches associated with frequent use of analgesics [83–86].

23.4.1.3 Opioids. Opioids have variable efficacy and are usually reserved as rescue medications or for specific situations like pregnancy, coronary artery disease, or other comorbidities that preclude the use of other drugs.

23.4.1.4 Ergots. Ergotamine and dihydroergotamine have serotonin agonist activity and are vasoconstrictors. Dihydroergotamine nasal spray has shown to be effective and well tolerated; other preparations are intramuscular, intravenous, oral tablet, sublingual, and suppository [87, 88].

23.4.1.5 Valproate. Intravenous valproate is also used as abortive treatment in migraines, but its effectiveness needs to be confirmed in randomized, double-blinded, placebo-controlled studies. The doses used in clinical practice are generally well tolerated [89, 90].

23.4.1.6 Antiemetics. Several antiemetic drugs are frequently used in acute migraine either to treat the associated nausea or for their effectiveness on the overall attack. The most common side effect seen with these drugs is sedation. Chlorpromazine, metoclopramide, and prochlorperazine, preferably in intravenous formulation, can be used, although there are some contradictory data [69, 94]. Antiemetics can also increase the effectiveness of other oral abortive drugs by improving delayed gastric emptying associated with acute attacks of migraine [95].

23.4.2 Preventive Therapy

Preventive medications are drugs taken on a daily basis to decrease the frequency, severity, and duration of attacks as well as to improve their responsiveness to abortive treatment and reduce disability. Many migraineurs require a prophylactic approach due to frequent or very debilitating attacks, lack of response to abortive treatment, or inability to use acute drugs due to comorbidities or interaction with other medications. Several groups of medications are used for preventive treatment of migraines: anticonvulsants, antidepressants, β -adrenergic blockers, Ca^{2+} channel blockers, botulinum toxin, and others.

23.4.2.1 Anticonvulsants. Migraines commonly coexist with other chronic neurological and psychiatric conditions. Some of these disorders, such as epilepsy, are also characterized by episodic attacks like migraines. Individuals with epilepsy have a twofold higher risk of suffering from migraine than those without epilepsy. Migraineurs have a higher risk of epilepsy than nonmigraineurs [96].

Several anticonvulsants drugs are also used for migraine prophylaxis. Only two are approved by the Food and Drug Administration (FDA) for such indication. Antiepileptic drugs are used for trigeminal neuralgia and are increasingly being used in migraine therapy [97–100]. While their mechanisms vary, many act via the γ -aminobutyric acid (GABA) system. For example, valproate elevates GABA levels [100]. Indeed, some trigeminal ganglion neurons contain GABA and many have GABA_A receptors [100]. We have found that both GABA_A and GABA_B receptors are present on cultured trigeminal ganglion neurons (unpublished observations). Whether any of these drugs act directly on the trigeminal nerves is speculative. It is generally believed that GABAergic antiepileptics act by inhibiting neural activity in the CNS. The study of these antiepileptic drugs is especially interesting because a better understanding of their mechanisms of action could throw some light on the pathophysiological mechanisms underlying migraine.

Valproate was the first antiepileptic drug approved by the FDA for migraine prophylaxis [101, 102]. The most common side effects of valproate are gastrointestinal, although asthenia, weight gain, alopecia, and tremor are also relatively frequent. Rarely, more severe idiosyncratic adverse reactions like hepatitis, pancreatitis, or hematological disorders can occur. Valproate is potentially teratogenic. An extended-release preparation allows taking valproate only once a day. The starting dose for valproate and all the anticonvulsants is followed by slow titration to an increased dosage.

Topiramate has shown efficacy in migraine prevention and has been the second and most recent antiepileptic drug approved by the FDA for this purpose [103–106]. Although the exact mechanism of action of topiramate is not fully understood, it is probably related to modulation of GABA and glutamate-mediated neurotransmission as well as its direct activity on α -amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA)/kainate glutamate receptors [97, 98]. The most common side effects are paresthesias, cognitive symptoms and sedation, nausea, anorexia, and weight loss.

Gabapentin is used for several neuropathic conditions as well as for migraine prophylaxis, although more studies are needed to support its use in migraine [69, 107]. Similar to other antiepileptics, Gabapentin is likely to have multiple mechanisms of

action, but these are not completely understood [97]. The most common side effects are somnolence and dizziness, which may be minimized by slow titration.

23.4.2.2 β -Blockers. The nonselective β blockers propranolol, timolol, and nadolol as well as the selective β_1 blockers atenolol and metoprolol are used in prevention of migraine. Their mechanism of action, although remaining unknown, is thought to be central, at least in part due to β_1 adrenoreceptor antagonism in the ventroposteromedial thalamus [108, 109].

The use of propranolol or timolol appears to be more effective than the other β blockers [110, 111]. Fatigue, depression, nausea, dizziness, and insomnia are the most frequent side effects, although they are usually well tolerated. Nonselective β blockers should not be used in patients with asthma or diabetes. A long-acting formulation of propranolol facilitates compliance by allowing once-a-day administration [112].

23.4.2.3 Antidepressants. While the mechanism of antidepressant drugs is not well understood, it is not thought to be due to its effect on underlying depression [113], although more studies are needed to confirm this [114]. Antidepressants produce a decrease in β -adrenergic receptor density and norepinephrine-stimulated cyclic adenosine monophosphate (cAMP) response [87].

Several tricyclic antidepressants (TCAs) are used for migraine prophylaxis: amitriptyline, nortriptyline, protriptyline, doxepin, and imipramine. TCAs upregulate the GABA_B receptor, downregulate the histamine receptor, and enhance the neuronal sensitivity to substance P. Some TCAs are 5-HT₂ receptor antagonists. Absorption, distribution, and excretion of TCAs are very variable; thus the dose must be individualized. These drugs frequently cause side effects due to their antimuscarinic, antihistaminic, and α -adrenergic activity. They should be used with caution in elderly patients and avoided in patients with arrhythmias due to potential cardiac toxicity. Amitriptyline is the best studied TCA and its use is recommended based on multiple consistent randomized clinical trials [69]. Nortriptyline is a metabolite of amitriptyline and is less sedating.

A second group of antidepressants used in migraine prophylaxis are the selective serotonin reuptake inhibitors (SSRIs): fluoxetine, fluvoxamine, paroxetine, sertraline, and citalopram. All of them have been used with variable results in prevention of migraine. These drugs have less antimuscarinic, antihistaminic, and cardiovascular side effects than TCAs, but the quality of evidence to support their recommendation is not as high as for TCAs [69].

Monoamine oxidase inhibitors (MAOIs) are a third group of antidepressants used in prevention of migraines. Phenelzine, a nonspecific inhibitor of MAO_A and MAO_B, is considered effective in migraine prophylaxis by experts, but the scientific data available are insufficient. Common side effects of MAOIs are insomnia, orthostatic hypotension, constipation, weight gain, and peripheral edema. Patients on MAOIs must follow a tyramine-restricted diet and avoid certain medications to prevent hypertensive crisis.

23.4.2.4 Calcium Channel Blockers. The strength of evidence to support the use of verapamil and nimodipine for prevention of migraines is not very strong, but these are relatively commonly used drugs. Similarly to what occurs with other prophylactic medications, the physiological mechanisms of action of calcium channel antagonists

are unclear. Verapamil is usually well tolerated. Constipation is one of the most common side effects. A sustained-release preparation facilitates compliance.

23.4.2.5 *Nonsteroidal Anti-Inflammatory Drugs.* Aspirin, ketoprofen, and naproxen can be used in prevention of migraine, although they are not as effective as some of the drugs previously mentioned and they might have significant gastrointestinal and renal side effects [108].

23.4.2.6 *Botulinum Toxin.* Pericranial injections of botulinum toxin type A (Botox) have recently been introduced as an alternative preventive option for migraine prophylaxis. The evidence available is somewhat inconsistent and further well-designed clinical trials are needed [91, 115].

23.4.2.7 *Other.* Feverfew is a medicinal herb with undetermined clinical effectiveness. Magnesium supplementation has been studied with contradictory results. The most common side effects were diarrhea and gastric irritation [116]. Riboflavin (vitamin B₂) at high doses is well tolerated and can be used for migraine prevention [117].

23.5 FUTURE DIRECTIONS

23.5.1 Potential for Targeted Repression of CGRP Synthesis

An understanding of the mechanisms by which trigeminal CGRP levels are regulated will allow the development of strategies to specifically lower CGRP levels for the treatment of craniofacial pain disorders such as migraine. We have proposed that MAP kinases are important regulators of CGRP synthesis (Fig. 23.2). 5-HT₁ receptor agonists can repress CGRP secretion [118] and MAP kinase activation of the 18-bp CGRP enhancer [77, 119]. Based on a recent study, neuronal extracellular regulated kinase (ERK) MAP kinase inhibitors may be a promising strategy for attenuating allodynia in neuropathic pain [120]. A corollary approach will be to stimulate MAP kinase phosphatases. We have found that overexpression of MAP kinase phosphatase-1 lowers CGRP promoter activity [119]. These observations support the significance of future attempts to inhibit MAP kinase activation of CGRP synthesis. A novel approach to repress expression of CGRP synthesis is through posttranscriptional gene silencing. RNA interference (RNAi), a recently described biological process involved in posttranscriptional control of gene expression, could be manipulated to degrade CGRP mRNA, thus preventing its translation into the peptide. Although still far from application in humans, the therapeutic use of RNAi in neurological diseases is currently being explored, and several successes have been described in different animal models of human disease [121].

23.5.2 Potential for CGRP Antagonists and Migraine Drugs for Other Forms of Pain

The role of trigeminal CGRP is of particular significance due to the prevalence of painful craniofacial disorders. For migraine alone, it is estimated that 18 million Americans, including almost one in every five women, suffer an estimated 4 million

attacks every week [18, 19]. The chronic pain often precipitates other serious conditions such as depression [122, 123], and there is an enormous financial burden in the billions per year. A large number of people also suffer from other craniofacial pains, with estimates ranging from 5 to 12% of the population [124].

The events in other craniofacial pains, such as the neuropathic pain of trigeminal neuralgia, are even less understood than in migraine [125–127]. Elevated CGRP is associated with temporomandibular joint (TMJ) disorders [128–131] and eye conditions following laser or ocular surgery trauma [132]. Outside the craniofacial structures, elevated CGRP is also associated with other disorders, such as some forms of hypertension [133] and sepsis [134].

Due to the high incidence and generally poor efficacy of current treatments for trigeminal and other chronic-pain disorders, there is a need for improved therapeutic and preventative measures. Some of the drugs used to prevent migraines are also effective in the management of other forms of pain. Specifically, diabetic neuropathy and postherpetic neuralgia have been extensively studied, and TCAs and gabapentin, among others, are frequently used for symptomatic relief in these conditions [135, 136]. In contrast, carbamazepine, which is effective in the treatment of neuropathic pain [137] and is a first-line drug in the management of trigeminal neuralgia [87], has not shown efficacy in the treatment of migraines [138]. It is tempting to speculate that CGRP receptor antagonists might be beneficial in treating other conditions that involve elevated CGRP. Whether CGRP receptor antagonists will be effective in treating these conditions will be of intense basic and clinical interest in the upcoming years.

PREFACE

Neuropharmacology is the study of drugs that affect the nervous system. This includes not only the identification of neuronal drug targets but also the study of basic mechanisms of neural function that may be amenable to pharmacological manipulation. Indeed, neuropharmacological drugs are commonly used as valuable tools to discover how nerve cells function and communicate in addition to therapeutic agents for the treatment of a wide variety of neuropsychiatric disorders. In fact, drugs that are used to treat disorders of the brain and nervous system represent one of the largest groups of approved therapeutic agents. Clearly the demand for drugs to treat disorders of the nervous system will only grow in the face of an aging population. Not surprisingly, almost all major pharmaceutical corporations and many biotechnology companies have extensive drug discovery programs in neuroscience and neuropharmacology. The recent pace of research and discovery in neuropharmacology and associated therapeutics has been quite rapid, as is true for most areas of biomedical research. Given this as well as the extremely broad nature of the field, we felt that it would be timely and important to develop a comprehensive handbook of neuropharmacology that would include state-of-art reviews covering both basic principles and novel approaches for clinical therapeutics.

Our approach for the organization of this handbook was primarily translational (bench to bedside) in nature. The three book volumes consist of 10 clinical sections, each consisting of 4–7 chapters devoted to various neuropsychiatric disorders, including mood, anxiety, and stress disorders, psychosis, pain, neurodegeneration, and many others. In most cases, these sections have introductory chapters providing background information and/or basic principles prior to presenting chapters covering state-of-the-art therapeutics. Volume I also contains a large introductory section consisting of 17 chapters on basic neuropharmacological subjects and principles. These include chapters on the history of neuropharmacology as well as intercellular and intracellular signaling followed by chapters covering all of the major neurotransmitter systems and other important signaling molecules, such as ion channels and transporters. Our objective for this project was to create a high-level reference work that will be useful to all practitioners of neuropharmacology ranging from graduate students, academicians, and clinicians to industrial scientists working in drug discovery. These volumes will be part of the John Wiley & Sons major reference work program and will be published online as well as in print. The online version of this handbook is expected to undergo frequent updates and additions in order to maintain its cutting-edge status.

The editors would like to thank all of the chapter contributors for their hard work and commitment to this project. We would also like to thank our managing editor, Jonathan Rose, at John Wiley & Sons for all of the valuable assistance that he has provided.

Contents

Preface	xi
Contributors	xiii

VOLUME 1

PART I BASIC NEUROPHARMACOLOGY	1
Chapter 1 Soup or Sparks: The History of Drugs and Synapses	3
<i>William Van der Kloot</i>	
Chapter 2 Synaptic Transmission: Intercellular Signaling	39
<i>J. David Jentsch and Robert H. Roth</i>	
Chapter 3 Synaptic Transmission: Intracellular Signaling	59
<i>R. Benjamin Free, Lisa A. Hazelwood, Yoon Namkung Michele L. Rankin, Elizabeth B. Rex, and David R. Sibley</i>	
Chapter 4 Neuronal Nicotinic Receptors: One Hundred Years of Progress	107
<i>Kenneth J. Kellar and Yingxian Xiao</i>	
Chapter 5 Muscarinic Acetylcholine Receptors	147
<i>Jürgen Wess</i>	
Chapter 6 Norepinephrine/Epinephrine	193
<i>Megan E. Kozisek and David B. Bylund</i>	
Chapter 7 Dopaminergic Neurotransmission	221
<i>John A. Schetz and David R. Sibley</i>	
Chapter 8 Serotonin Systems	257
<i>John A. Gray and Bryan L. Roth</i>	
Chapter 9 Neuropharmacology of Histamine in Brain	299
<i>Raphaël Faucard and Jean-Charles Schwartz</i>	

Chapter 10	Ionotropic Glutamate Receptors	365
	<i>David Bleakman, Andrew Alt, David Lodge, Daniel T. Monaghan, David E. Jane, and Eric S. Nisenbaum</i>	
Chapter 11	Metabotropic Glutamate Receptors	421
	<i>James A. Monn, Michael P. Johnson, and Darryle D. Schoepp</i>	
Chapter 12	Pharmacology of the GABA_A Receptor	465
	<i>Dmytro Berezhnoy, Maria C. Gravielle, and David H. Farb</i>	
Chapter 13	Metabotropic GABA Receptors	569
	<i>Martin Gassmann and Bernhard Bettler</i>	
Chapter 14	Voltage-Gated Ion Channels	617
	<i>Alex Fay, Patrick C. G. Haddick, and Lily Yeh Jan</i>	
Chapter 15	Neuropeptides	669
	<i>Fleur L. Strand</i>	
Chapter 16	Neurotransmitter Transporters	705
	<i>Jia Hu, Katherine Leitzell, Dan Wang, and Michael W. Quick</i>	
Chapter 17	Gaseous Signaling: Nitric Oxide and Carbon Monoxide as Messenger Molecules	743
	<i>Kenny K. K. Chung, Valina L. Dawson, and Ted M. Dawson</i>	
PART II	MOOD DISORDERS	763
Chapter 18	Neurobiology and Treatment of Depression	765
	<i>Alexander Neumeister, Dennis S. Charney, Gerard Sanacora, and John H. Krystal</i>	
Chapter 19	Neurotrophic Factors in Etiology and Treatment of Mood Disorders	789
	<i>Ronald S. Duman</i>	
Chapter 20	Antidepressant Treatment and Hippocampal Neurogenesis: Monoamine and Stress Hypotheses of Depression Converge	821
	<i>Alex Dranovsky and René Hen</i>	
Chapter 21	Neuroendocrine Abnormalities in Women with Depression Linked to the Reproductive Cycle	843
	<i>Barbara L. Parry, Charles J. Meliska, L. Fernando Martinez, Eva L. Maurer, Ana M. Lopez, and Diane L. Sorenson</i>	
Chapter 22	Neurobiology and Pharmacotherapy of Bipolar Disorder	859
	<i>R. H. Belmaker, G. Agam, and R. H. Lenox</i>	
Index		877
Cumulative Index		915

VOLUME 2

PART I	ANXIETY AND STRESS DISORDERS	1
Chapter 1	Neurobiology of Anxiety	3
	<i>Miklos Toth and Bojana Zupan</i>	
Chapter 2	Pharmacotherapy of Anxiety	59
	<i>Jon R. Nash and David J. Nutt</i>	
Chapter 3	Benzodiazepines	93
	<i>Hartmut Lüddens and Esa R. Korpi</i>	
Chapter 4	Neuroactive Steroids in Anxiety and Stress	133
	<i>Deborah A. Finn and Robert H. Purdy</i>	
Chapter 5	Emerging Anxiolytics: Corticotropin-Releasing Factor Receptor Antagonists	177
	<i>Dimitri E. Grigoriadis and Samuel R. J. Hoare</i>	
Chapter 6	Neurobiology and Pharmacotherapy of Obsessive-Compulsive Disorder	215
	<i>Judith L. Rapoport and Gale Inoff-Germain</i>	
PART II	SCHIZOPHRENIA AND PSYCHOSIS	249
Chapter 7	Phenomenology and Clinical Science of Schizophrenia	251
	<i>Subroto Ghose and Carol Tamminga</i>	
Chapter 8	Dopamine and Glutamate Hypotheses of Schizophrenia	283
	<i>Bitá Moghaddam and Houman Homayoun</i>	
Chapter 9	Molecular Genetics of Schizophrenia	321
	<i>Liam Carroll, Michael C. O'Donovan, and Michael J. Owen</i>	
Chapter 10	Postmortem Brain Studies: Focus on Susceptibility Genes in Schizophrenia	343
	<i>Shiny V. Mathew, Shruti N. Mitkus, Barbara K. Lipska, Thomas M. Hyde, and Joel E. Kleinman</i>	
Chapter 11	Pharmacotherapy of Schizophrenia	369
	<i>Zafar Sharif, Seiya Miyamoto, and Jeffrey A. Lieberman</i>	
Chapter 12	Atypical Antipsychotic Drugs: Mechanism of Action	411
	<i>Herbert Y. Meltzer</i>	

PART III	SUBSTANCE ABUSE AND ADDICTIVE DISORDERS	449
Chapter 13	Introduction to Addictive Disorders: Implications for Pharmacotherapies	451
	<i>Mary Jeanne Kreek</i>	
Chapter 14	Dopaminergic and GABAergic Regulation of Alcohol-Motivated Behaviors: Novel Neuroanatomical Substrates	465
	<i>Harry L. June and William J. A. Eiler II</i>	
Chapter 15	Nicotine	535
	<i>August R. Buchhalter, Reginald V. Fant, and Jack E. Henningfield</i>	
Chapter 16	Psychostimulants	567
	<i>Leonard L. Howell and Heather L. Kimmel</i>	
Chapter 17	MDMA and Other “Club Drugs”	613
	<i>M. Isabel Colado, Esther O’Shea, and A. Richard Green</i>	
Chapter 18	Marijuana: Pharmacology and Interaction with the Endocannabinoid System	659
	<i>Jenny L. Wiley and Billy R. Martin</i>	
Chapter 19	Opiates and Addiction	691
	<i>Frank J. Vocci</i>	
PART IV	PAIN	707
Chapter 20	Neuronal Pathways for Pain Processing	709
	<i>Gavril W. Pasternak and Yahong Zhang</i>	
Chapter 21	Vanilloid Receptor Pathways	727
	<i>Makoto Tominaga</i>	
Chapter 22	Opioid Receptors	745
	<i>Gavril W. Pasternak</i>	
Chapter 23	Advent of A New Generation of Antimigraine Medications	757
	<i>Ana Recober and Andrew F. Russo</i>	
	Index	779
	Cumulative Index	817
VOLUME 3		
PART I	SLEEP AND AROUSAL	1
Chapter 1	Function and Pharmacology of Circadian Clocks	3
	<i>Gabriella B. Lundkvist and Gene D. Block</i>	

Chapter 2	Melatonin Receptors in Central Nervous System	37
	<i>Margarita L. Dubocovich</i>	
Chapter 3	Narcolepsy: Neuropharmacological Aspects	79
	<i>Seiji Nishino</i>	
Chapter 4	Hypocretin/Orexin System	125
	<i>J. Gregor Sutcliffe and Luis de Lecea</i>	
Chapter 5	Prokineticins: New Pair of Regulatory Peptides	163
	<i>Michelle Y. Cheng and Qun-Yong Zhou</i>	
Chapter 6	Sedatives and Hypnotics	177
	<i>Keith A. Wafford and Paul J. Whiting</i>	
PART II	DEVELOPMENT AND DEVELOPMENTAL DISORDERS	201
Chapter 7	Regulation of Adult Neurogenesis	203
	<i>Heather A. Cameron</i>	
Chapter 8	Neurotrophic Factors	221
	<i>Franz F. Hefti and Patricia A. Walicke</i>	
Chapter 9	Neurotrophins and Their Receptors	237
	<i>Mark Bothwell</i>	
Chapter 10	Tourette's Syndrome and Pharmacotherapy	263
	<i>Pieter Joost van Watum and James F. Leckman</i>	
Chapter 11	Neuropharmacology of Attention-Deficit/Hyperactivity Disorder	291
	<i>Paul E. A. Glaser, F. Xavier Castellanos, and Daniel S. Margulies</i>	
Chapter 12	Psychopharmacology of Autism Spectrum Disorders	319
	<i>Adriana Di Martino, Steven G. Dickstein, Alessandro Zuddas, and F. Xavier Castellanos</i>	
PART III	NEURODEGENERATIVE AND SEIZURE DISORDERS	345
Chapter 13	Stroke: Mechanisms of Excitotoxicity and Approaches for Therapy	347
	<i>Michael J. O'Neill, David Lodge, and James McCulloch</i>	
Chapter 14	Epilepsy: Mechanisms of Drug Action and Clinical Treatment	403
	<i>William H. Theodore and Michael A. Rogawski</i>	
Chapter 15	Pharmacotherapy for Traumatic Brain Injury	443
	<i>Donald G. Stein and Stuart W. Hoffman</i>	
Chapter 16	Dementia and Pharmacotherapy: Memory Drugs	461
	<i>Jerry J. Buccafusco</i>	

Chapter 17	Pharmacotherapy and Treatment of Parkinson's Disease	479
	<i>Wing Lok Au and Donald B. Calne</i>	
Chapter 18	Parkinson's Disease: Genetics and Pathogenesis	523
	<i>Claudia M. Testa</i>	
Chapter 19	Invertebrates as Powerful Genetic Models for Human Neurodegenerative Diseases	567
	<i>Richard Nass and Charles D. Nichols</i>	
PART IV	NEUROIMMUNOLOGY	589
Chapter 20	Myelin Lipids and Proteins: Structure, Function, and Roles in Neurological Disorders	591
	<i>Richard H. Quarles</i>	
Chapter 21	Pharmacology of Inflammation	621
	<i>Carmen Espejo and Roland Martin</i>	
Chapter 22	Pharmacological Treatment of Multiple Sclerosis	671
	<i>B. Mark Keegan</i>	
Chapter 23	Novel Therapies for Multiple Sclerosis	683
	<i>Martin S. Weber and Scott S. Zamvil</i>	
Chapter 24	Neuropharmacology of HIV/AIDS	693
	<i>Sidney A. Houff and Eugene O. Major</i>	
PART V	EATING AND METABOLIC DISORDERS	731
Chapter 25	Leptin: A Metabolic Perspective	733
	<i>Dawn M. Penn, Cherie R. Rooks, and Ruth B. S. Harris</i>	
Chapter 26	Ghrelin: Structural and Functional Properties	765
	<i>Birgitte Holst, Kristoffer Egerod, and Thue W. Schwartz</i>	
Chapter 27	Mechanisms Controlling Adipose Tissue Metabolism by the Sympathetic Nervous System: Anatomical and Molecular Aspects	785
	<i>Sheila Collins, Renato H. Migliorini, and Timothy J. Bartness</i>	
Chapter 28	Antiobesity Pharmacotherapy: Current Treatment Options and Future Perspectives	815
	<i>Yuguang Shi</i>

1.1 FUNCTIONAL IMPORTANCE OF CIRCADIAN RHYTHMS

Biological molecules interact in space and in time. Understanding spatial relationships in biology has been fundamental to our comprehension of how function follows form. The study of time in biology (“temporal biology”) is a more recent area of inquiry; however, it has become increasingly clear that timing is a fundamental attribute of living systems. Organisms have the capacity to generate oscillations in physiology and behavior over a wide time domain. Subsets of biological oscillations have period lengths that match major environmental cycles and consequently can be used as internal chronometers matching the external periodicity. Most common among the biological rhythms are circadian rhythms, periodicities of approximately 24 h.

Biological clocks, expressing periodicities within the circadian domain, exert a profound effect on behavior and physiology, creating a “day within” [1] that allows organisms to prepare in advance of environmental changes. In higher animals, including mammals, biological timers orchestrate cycles of sleep and wakefulness, rhythmicity in major hormonal systems, as well as periodic fluctuations in cognitive performance, blood pressure, and response to drug administration [2]. Circadian clocks also play a less obvious but sophisticated role in the solar navigation behavior displayed by species of bees, birds, reptiles, and amphibians. Honeybees, for example, rely on the biological clock to use the sun as a compass for navigation [3]. Similar to bees, several species of birds use the position of the sun as a compass in navigating terrain. A properly set biological clock is critical for interpreting the sun’s azimuth and a bird synchronized to an altered light schedule will make errors in flight orientation proportional to the number of hours the biological clock is set away from local time [4].

Circadian clocks also play an unexpected but critical role in the seasonal timing of flowering in many plants and reproductive cycles in animals. Although some animals possess approximately 12-month timers (circannual rhythms), other animals rely on a circadian clock to measure day length or night length. Some mammals, including several rodent species, exhibit seasonal reproductive rhythms that use a circadian clock to generate appropriate seasonal responses. Such animals have an underlying circadian “sensitivity rhythm” to light. Although the exact mechanism is uncertain, the circadian sensitivity rhythm allows the system to determine whether the seasonal light cycle consists of short or long days [5].

1.2 PROPERTIES OF CIRCADIAN CLOCKS

1.2.1 Circadian Rhythms

When measured under constant environmental conditions, most higher organisms exhibit activity–rest cycles as well as a multitude of rhythmic physiological parameters. In humans there is a pronounced sleep–wakefulness rhythm, a rhythm in body temperature, and rhythms in cognitive performance [6]. Little escapes the influence of the circadian timer. Much of the research on circadian clocks in mammals has been performed in rodent models. Many rodents exhibit precise rhythms in wheel-running activity, and this has frequently been used as a convenient rhythm for measuring the properties of the circadian timing system [7]. If the running

wheel is housed in constant darkness, most rodent species will exhibit a periodicity slightly less than 24 h. Such rhythms are referred to as “free-running” and are the expression of the circadian timing system without being influenced by environmental synchronizing signals.

1.2.2 Temperature Sensitivity

Not surprisingly, in order to be a faithful chronometer, the biological clock must not change frequency at different environmental temperatures. In mammals there is obvious thermal buffering due to active homeostatic control of body temperature. Nonetheless, both in homoeothermic and poikilothermic organisms, the circadian clock is relatively insensitive to ambient temperatures within the normal environmental range [8]. The Q_{10} measurements (response of the clock period to 10-degree temperature changes) are ‘close to 1, indicating near constancy’ of period over a 10-degree change. In contrast, many biochemical reactions have Q_{10} ’s of 2 or greater (doubling or greater of reaction rate). It is not true, however, that circadian clocks are temperature insensitive. Many organisms respond to a temperature step with a shift in the phase of the rhythm and many clocks can be synchronized by periodic temperature cycles [9]. It is evident that the relative temperature independence that is observed at any constant temperature does not reflect insensitivity to temperature but rather some form of temperature compensatory mechanism.

1.2.3 “Entrainment” Properties

If rodents are maintained on 24-hr light–dark (LD) cycles, the circadian rhythm in locomotor activity adopts the period of the 24-h light schedule. This process synchronizes (i.e., “entrains”) the circadian clock to the 24-h solar cycle and, importantly, sets the phase of the clock to “local time” (activity occurs in relation to the local day–night cycle). Except for measuring the lapse of time (e.g., a “stopwatch”), clocks must be set to local time to be truly useful. There are several phenomenological models that have helped to explain the synchronization, or entrainment, process. Entrainment appears to occur primarily through rapid changes in the phase of the clock brought about by light–dark transitions in the light cycle [10, 11]. The so-called nonparametric model for entrainment postulates that the transition at dawn leads to a rapid phase advance of the clock and the transition to dusk leads to a phase delay [10, 12]. The two phase shifts are typically not equal in magnitude and the net phase shift equals the difference between the 24-h light cycle and the period of the biological clock. Elegant in its simplicity, the model has been useful in focusing on the importance of rapid phase adjustments on the entrainment process. These authors recognized that entrainment was more complex than simply rapid phase adjustments at dawn and dusk, and more recent work has helped inform the model by taking into account the more subtle effect of light on the clock’s period [13].

1.2.4 Aschoff’s Rules

Although the free-running period is under genetic control and varies among species, the precise period may vary depending upon constant conditions and the prior light history. Jürgen Aschoff explored the effects of constant light on the free-running

period [14]. Numerous studies in a wide range of species led to a set of empirical generalities about the effects of different-intensity light on the free-running rhythm. Known as *Aschoff's rules*, these observations noted that diurnal and nocturnal animals respond differently to increasing the intensity of constant light [2]. Nocturnal animals tend to exhibit longer free-running periods as the intensity of light increases whereas the rhythms of diurnal animals tended to shorten in brighter constant light. Also the ratio of activity time compared to rest time increased in diurnal animals as light intensity increased and decreased in nocturnal animals. Finally, in general but with exceptions, diurnal animals tend to have free-running periods longer than 24 h in constant darkness and nocturnal animals tend to have periods of less than 24 h. These observations made it clear that the free-running period of locomotor activity in a rodent was a function of the constant photic/nonphotic environment to which it was exposed. It has been proposed that the change in free-running period in response to long light pulses is probably part of the mechanism by which light cycles act to adjust the free-running period to match more closely the period of the light cycle [13, 15].

1.2.5 Aftereffects

In addition to changes in free-running period associated with the current photic environment, the biological clock may be influenced by the prior history [16]. Several types of history-dependent effects are observed, depending upon the species. Mice or hamsters exposed to short or long photoperiods (representing long spring or short winter days) exhibit different durations of locomotor activity and different free-running periods when subsequently placed into constant darkness [12, 16]. In addition, animals exposed to light cycle periods either shorter or longer than 24 h subsequently exhibit free-running periods in constant darkness positively correlated with the prior light cycle period. Thus, both the free-running period and the waveform of the circadian rhythm are influenced by prior photic history. Although the function of such “aftereffects” is not fully understood, it has been proposed that this mechanism may be centrally involved in period adjustments that contribute to stable entrainment [10].

1.3 STRUCTURE OF CIRCADIAN TIMING SYSTEM IN NONMAMMALIAN MODELS

Much of what we know about the mechanisms underlying circadian timing comes from studies on nonmammalian models. While organisms in nearly all phyla have been investigated, a few models have emerged as preeminent for study at different levels of circadian organization. At the molecular level, *Drosophila* (fruitfly) has provided the most detailed and satisfying model of the molecular components that interact to generate a 24-h periodicity. Marine mollusks, notably *Aplysia* (sea hare) and *Bulla* (cloudy bubble snail), have provided cellular/biophysical mechanisms involved in the synchronization and expression of circadian rhythms. Additional models, such as the cockroach, have yielded important insights into the system-level organization underlying circadian rhythms. Much of what we have learned from these model systems has informed similar discoveries in mammals.

1.3.1 Molecular Basis of Rhythmicity: *Drosophila*

Although many aspects of circadian timing have been studied in insects, perhaps the greatest contribution of insects to understanding circadian rhythmicity comes from molecular/genetic studies in *Drosophila*. Early phenomenological analysis in *Drosophila* provided the foundations for understanding the synchronization process by light cycles [12]. However, the focus of research and pace of discovery was fundamentally changed by the isolation of long-period, short-period, and arrhythmic mutants, all of which turned out to be alleles of the same gene, referred to as *period* [17]. Subsequent mutagenesis, isolation and cloning yielded several additional “clock genes” including *timeless*, *doubletime*, *clock*, *cycle*, and *cryptochrome* [18]. Although the *Drosophila* clock model continues to develop, a working hypothesis has been elaborated in which clock genes and their products form inhibitory and excitatory feedback loops which together generate a stable circadian period [18, 19].

1.3.2 Drug Effects in *Drosophila*

The fruit fly, *Drosophila melanogaster*, represents a “simple” genetic model in which to study pathways modulating responses to drugs of abuse. Flies respond to a number of drugs of abuse with motor responses that strikingly resemble those seen in vertebrate models: Exposure to ethanol leads to transient motor activation followed by sedation [20–23]. Exposure to the psychomotor stimulant cocaine leads to extensive stereotypic motor patterns, including reflexive grooming, locomotion, and at high doses hyperactive behaviors, including wing buzzing, that are termed “seizures” in the fly literature [21, 24]. Additionally, flies can show enhanced responses to repeated doses of cocaine, a process called sensitization [24], and tolerance to repeated doses of ethanol [25, 26]. Tolerance and sensitization are responses seen in animal models and humans that are thought to reflect the altered homeostatic responses that develop with repeated drug exposures. Sensitization is thought to contribute to the addictive process [27, 28] and is rather commonly used as an indirect correlate of craving.

One obvious question when using the fly as a model for these complex animal behaviors regards the relevance of the model. It is now clear that many similar pathways are involved relative to vertebrates, including dopamine and/or serotonin, which modulate responses to cocaine, ethanol, and nicotine [21, 29], and G-protein and protein kinase A signaling, which modulate responses to cocaine [29, 30]. This, along with work showing cyclic adenosine monophosphate (cAMP) pathway involvement in ethanol responses [20, 30, 31], further increases the parallels between the signaling pathways underlying responses to drugs of abuse between flies and higher vertebrates [32].

The real interest in the fly as a model is to define novel pathways that would not have necessarily been uncovered in vertebrates. One pathway pioneered in the fly is the involvement of the circadian gene pathway in modulating responses to cocaine, particularly the sensitization to repeated cocaine exposures, which requires most but not all of the circadian genes in the fly [33–35]. This observation now has validation in mouse knockouts [36]. Mice have three *period* genes, of which *mper2* is the major circadian *per* gene. The *per2* knockouts show somewhat enhanced conditioned place preference (CPP) and locomotor sensitization, but *mper1* knockouts show loss of

both CPP and sensitization. Given that *mper2* knockouts show a more severe circadian phenotype than *mper1* [37–39], this implies a separation of circadian and drug reward roles for these genes. In addition, *clock* mutant mice demonstrate enhanced CPP to cocaine, and enhanced excitability of ventral tegmental area (VTA) dopamine neurons [40]. Given that the VTA–nucleus accumbens dopamine tract is not central to circadian rhythmicity in the mouse, this again implies noncircadian functions of these circadian genes in function of the reward pathways.

1.3.3 Cellular Basis of Rhythmicity: Molluscan Retina

The eye of the opisthobranch mollusks, *Aplysia* and *Bulla*, contain circadian pacemakers [41, 42]. The molluscan eye model has provided many firsts in chronobiological research. As an example, mollusks led the way in confirming the cell autonomous nature of circadian pacemakers within the nervous system [46]. The presence of “chronomodulators,” such as serotonin, (5-HT) in the regulation of the pacemaker phase was first revealed in *Aplysia*. The *Aplysia* and *Bulla* mollusks provided the first reliable in vitro model for evaluating the effects of pharmacological agents on the circadian clock [43]. Intracellular recordings in molluscan clock neurons provided important information about the biophysical and intracellular processes mediating pacemaker synchronization and expression. Mollusks also provided the first in vitro models for studying circadian multioscillator coupling. Impressively, much of what has been learned from mollusks has proven directly relevant to the mammalian timing system.

1.3.4 Circadian Rhythmicity: A Cell Autonomous Property

The first demonstration that individual neurons could act as circadian pacemakers was accomplished in the molluscan retina. Experiments in which the *Bulla* retina was surgically reduced localized the circadian clock to a group of approximately 100 pacemaker neurons located at the base of the retina [44]. The demonstration of the cell autonomous nature of neuronal circadian pacemakers was accomplished by taking advantage of the fact that the pacemaker neurons of the *Bulla* retina, referred to as BRNs (basal retinal neurons), exhibit a pronounced (up to 50%) rhythm in membrane conductance with membrane conductance low during the subjective day when compared with the subjective night [45]. BRNs, either in dispersed cell culture or when completely isolated in microwell dishes, exhibited a similar circadian rhythm in conductance [46]. The persistence of daily membrane conductance changes in isolated neurons confirmed that circadian rhythm generation is a property of individual neurons. This observation was later confirmed in dispersed *Aplysia* neurons, although the cells were never fully isolated [47].

1.3.5 Synchronization and Modulation of Clock Neurons

The identification of “clock neurons” in *Bulla* and *Aplysia* opened up important opportunities for the study of the mechanisms underlying pacemaker synchronization and expression. A large number of studies by several laboratories led to a simple hypothesis that phase control of the retinal clock is effected by changes in membrane

potential and modulation of a transmembrane calcium (Ca^{2+}) flux [48]. In this model, light cycles lead to membrane depolarization and phase adjustments during the early and late night. Another class of entrainment stimuli, Phe-Met-Arg-Phe-amine (FRMF)-amide (Phe-Met-Arg-Phe- NH_2) in *Bulla* [49] and 5-HT and cAMP in *Aplysia*, [50], generate phase shifts that are displaced by 180° on the time axis compared with light-induced shifts; that is, phase delays occur in the early subjective day and phase advances occur in the late subjective day. These treatments lead to membrane hyperpolarization and a reduction of Ca^{2+} influx presumably due to the reduction of impulse production during the subjective day. The model is attractive in that it proposes that all synchronization signals to the clock converge on a single process, an increase or decrease in a transmembrane Ca^{2+} flux. In addition to acting as phase-shifting agents, both 5-HT and FMRF-amide can modulate light-induced phase shifts [49, 51]. Serotonin's action can be complex, both attenuating and amplifying the effects of light, depending upon the phase at which it is present [52].

1.3.6 Ionic Currents Involved in Circadian Rhythmicity

Pacemaker expression involves rhythmic modulation of potassium (K^+) conductance(s). The ability to make intracellular recordings from *Bulla* pacemaker neurons provided an opportunity to study circadian modulation in membrane phenomena. *Bulla* pacemaker neurons exhibit a circadian rhythm in the membrane potential [53]. Cells are relatively hyperpolarized during the subjective night and depolarized at subjective dawn. The membrane potential rhythm is associated with a rhythm in membrane conductance. Membrane conductance is higher during the subjective night when the BRNs are hyperpolarized [45, 48]. Application of tetraethylammonium (TEA) returns the subjective night conductance levels to subjective day time levels suggesting that K^+ channels play a critical role in the circadian rhythm in membrane conductance [46].

More recently, attempts have been made to identify specific potassium channels that are being modulated by the circadian pacemaker [54]. Three components of outward K^+ current have been identified: a transient outward current (I_A), a Ca^{2+} -dependent K^+ current ($I_{\text{K(Ca)}}$), and a sustained Ca^{2+} -independent current including the delayed rectifier, I_K . Whole-cell currents recorded before and after the projected dawn and normalized to the cell capacitance reveal a circadian modulation in the delayed rectifier current (I_K). However, the I_A and the $I_{\text{K(Ca)}}$ currents are not affected by the circadian pacemaker. The kinetics of the delayed rectifier suggest that it is not responsible for the rise in membrane potential near subjective dawn. Thus, other as-yet-unidentified K^+ conductances probably play this important role.

Similar results have been obtained with pacemaker cells in the retina of *Aplysia californica* [55]. *Aplysia* retinal neurons exhibit a decrease in the amplitude of a delayed rectifier current, measured in dispersed retinal cells, recorded at subjective dawn. As with the study in *Bulla*, experiments in *Aplysia* find no evidence for a circadian rhythm in I_A .

Perhaps the most satisfying and surprising outcome of the work on the molluscan eye is the ongoing discovery of how well conserved the cellular/biophysical circadian mechanisms are between the mollusks and mammals. With both the synchronization and expression pathways, similar ionic fluxes, conductances, and neuromodulatory pathways appear to be involved in regulation of the circadian system (see below).

1.3.7 System-Level Properties: Cockroach

Circadian systems are multioscillator in composition. At the level of pacemaker structures, such as the retina of mollusks or the suprachiasmatic nucleus (SCN) of the mammal, there are many neurons that are independently capable of generating a circadian periodicity. There is also the issue of paired pacemaker structures, by virtue of the fact that clocks can be located in eyes or in brain structures that are bilaterally symmetric. Beyond symmetric clock loci, there is evidence that many tissues can exhibit some level of rhythmicity, even when there are dominant tissues that serve as pacemakers. This complexity leads us to hypothesize the presence of both bilateral and hierarchical oscillator coupling relationships. Again, nonmammalian models, especially the cockroach, have given us significant insight into the organizational properties of circadian systems.

In the cockroach, the primary clock controlling activity–rest cycles is located within the optic lobe [56]. The clocks in the two optic lobes are coupled to one another. First, the activity–rest cycle is lengthened slightly when either lobe is removed, suggesting that the two clocks mutually accelerate one another when both are present [57]. More directly, if the clock of one lobe is delayed by several hours by cooling the lobe with a localized cooling probe, the other lobe will cause the cooled lobe to advance, while it is itself delayed [58]. The data suggest that the two lobes are mutually coupled and lead to a free-running period that is slightly shorter than either individual lobe. Beyond mutual entrainment of the bilaterally symmetric optic lobes, there appears to be a damped circadian oscillator that persists in the absence of the central optic lobe clocks. Lobeless animals, although arrhythmic on light cycles, can be driven to rhythmicity by temperature cycles [59]. The fact that the phase relationship between the locomotor rhythm and the temperature cycle changes as a function of the period of the thermocycle indicates the presence of a highly damped circadian oscillator. A model has emerged of central timers in the optic lobes that drive damped circadian oscillators in thoracic ganglia. The damped oscillators are more directly responsible for controlling the activity–rest cycle. The basic model of bilaterally symmetric central clocks controlling behavior and physiology through peripheral, perhaps highly damped clocks is an organizational principle that appears to be quite general, including mammals.

1.4 STRUCTURE OF CIRCADIAN TIMING SYSTEM IN MAMMALS

1.4.1 Suprachiasmatic Nucleus: A Central Circadian Timer

There are few examples in neuroscience research where it has been possible to unambiguously identify a restricted portion of the mammalian central nervous system as the locus of the generation and control of a complex behavior. The SCN is such a site. The SCN is a bilaterally symmetric structure lying just above the optic chiasm (Fig. 1.1). Each nuclei consists of approximately 10,000 neurons packed into a volume of about 0.5 mm^3 [60, 61]. The discovery of the SCN occurred with the efforts of two laboratories focused on identifying the pathways involved in synchronization of the circadian clock by light cycles, one laboratory looking for pathways controlling the circadian rhythm in drinking behavior [62], the other looking at pathways involved in adrenal corticosterone rhythmicity [63]. Both discovered that lesions placed above the optic chiasm led to disruption of the respective circadian

Figure 1.1 Mammalian circadian system. The internal master clock, located in the SCN in the hypothalamus in close vicinity to the third ventricle (3V), is primarily synchronized by the environmental light–dark cycle via a monosynaptic pathway in the retinohypothalamic tract (RHT). Retinal afferents reach the optic chiasm (OC) and the ventral “core” region of the SCN that contains vasoactive intestinal polypeptide (VIP). The dorsal “shell” region contains vasopressin (AVP) where most efferents to other brain regions are located. Activities of individual single-oscillator neurons are synchronized in the SCN synaptic network, giving a circadian output that drives physiological rhythms such as spontaneous neuronal activity, drug susceptibility, immune functions, and the rest–activity cycle. (See color insert.)

rhythms. The central importance of the region was firmly established by a number of experiments in which circadian rhythms in electrical activity were recorded from this region when isolated either with knife cuts from the rest of the brain [64] or by removing the SCN and recording from an SCN brain slice in vitro [65]. These experiments demonstrated that the SCN was intrinsically rhythmic and was presumably responsible for driving rhythmicity in other regions of the brain. An unambiguous demonstration of the importance of the SCN in controlling behavior occurred through transplantation experiments in which the SCN of fetal animals was transplanted into the third ventricle of the brains of adult animals with prior lesions to their SCN [66]. Rhythmicity was restored, and critically the host took on the period of the donor’s SCN. This was demonstrated through the use of a mutant hamster (*Tau* mutant) with an unusually short periodicity. Wild-type hamsters receiving the *Tau* mutant SCN exhibited short free-running periods whereas *Tau* mutant hamsters receiving the wild-type SCN exhibited longer periods. This provided an unambiguous demonstration that the SCN is responsible for generating and, to a large extent, setting the period of the animal’s activity rhythm.

1.4.2 Circadian Rhythms: Generated by Molecular Feedback Loops

Circadian rhythm generation is a property of individual neurons [46, 67]. We now know that several genes and their protein products are central to the generation of circadian rhythms. Much of the work in mammals has been informed by studies in *Drosophila* where there is similarity in underlying molecular mechanisms.

In mammals, the timing cycle is complex, with several feedback loops both positive and negative [68]. A core element in generating oscillators is the negative-feedback

loop involving a small group of genes and their protein products. This timing cycle is driven and the period determined primarily by a negative feedback loop with delay. A completed cycle involves the following steps [69]. The proteins CLOCK and BMAL1 form protein heterodimers. The CLOCK/BMAL1 complex enters the nucleus. The CLOCK/BMAL1 binds to E-box enhancer elements of *pers*, *crys*, and *Rev-Erb- α* . The binding leads to the expression of these clock genes and synthesis of the proteins PER, CRY, and REV-ERB- α . PER and CRY form homodimers and heterodimers in the cytoplasm and, when dimerized, enter the nucleus. At the same time, PER is continually phosphorylated by CKI-EPSILON, which leads to degradation, thus slowing the entry of PER into the nucleus. PER:CRY and CRY:CRY represses CLOCK:BMAL1-driven transcription of *pers* and *crys*. Thus, the negative-feedback loop is completed, as the protein products inhibit their own transcription. The long time constants for the transcriptional/translational rhythm are probably generated from several sources, including the phosphorylation of PER leading to its degradation and slowing of nuclear entry, PER:TIM's action on repressing *Per* transcription, and CRY protein inhibition of H3 histone acetylation by P300.

1.4.3 Role of Membrane Activity in Circadian Rhythm Generation

Membrane phenomena, including membrane potential, electrical impulses, and voltage-controlled ionic fluxes, have generally been considered as components of the “input pathway” and “output pathway” by which a transcription/translation-based clock receives temporal information from the environment and transmits rhythmic signals to other oscillators within the tissue and beyond. This long-held view has been challenged from time to time [70]. Perhaps the most direct challenge comes from studies in *Drosophila* [71–73] which revealed that when lateral neurons, circadian pacemaker neurons, are electrically silenced by expression of additional potassium channels, the molecular clockwork and the behavior become arrhythmic. The findings in *Drosophila* have brought new attention and focus to a possible role for membrane potential and associated transmembrane ionic fluxes in rhythm generation. Recent experiments conducted in our laboratory [74] reveal a critical role for a daily transmembrane Ca^{2+} flux in sustaining *mpc1* rhythmicity in the SCN and peripheral tissues. The precise relationship between membrane currents, Ca^{2+} oscillations, and molecular feedback loops is currently unclear.

1.4.4 Output Pathways of SCN

In order for the SCN to perform work for the organism as a central timer, it must influence other brain regions and peripheral targets via its output pathways. Most of the SCN's output is confined to the hypothalamus, and given the importance of the SCN in regulating physiology and behavior, the output pathways are surprisingly sparse and confined largely to the hypothalamus [75]. The SCN plays an important role in the regulation of sleep and appears to exert its effect on sleep primarily through projections to the subparaventricular zone and secondary connections to the dorsomedial hypothalamic nucleus which projects to brain regions involved in the regulation of sleep–wake behavior [76]. Lesions to the dorsomedial nucleus

eliminate rhythms in sleep, locomotor, feeding, and corticosteroid rhythms but not melatonin and body temperature [77].

The SCN also projects to the paraventricular hypothalamic nucleus in regulating melatonin (MT) synthesis. Regulation of the pineal gland is indirect [78]. The pathway leads to inhibition of MT synthesis during the day, when the SCN is active, and release from inhibition at night. As with many of the outputs from the SCN, the pathways are reciprocal. MT can inhibit SCN electrical activity via the MT1 receptor [78].

The SCN may also exert its action via diffusible signals. SCN transplantation experiments revealed that SCNs that were encapsulated in a polymer, preventing neural outgrowth, were capable of restoring locomotor rhythmicity in SCN lesioned hamsters [79]. Two diffusible mediators have been identified that may play key roles in the circadian regulation of physiology and behavior. Transforming growth factor (TGF- α) exhibits a circadian rhythm within the SCN and infusion of TGF- α into the third ventricle leads to inhibition of wheel running and sleep and body temperature rhythmicity [80]. A second diffusible factor, prokineticin 2, is a secreted protein that exhibits a circadian rhythm in the SCN with higher levels expressed during the subjective day. As with TGF- α , injection of prokineticin 2 into the brain results in inhibition of locomotor activity [81].

1.5 AGENTS THAT AFFECT PERIOD AND PHASE OF SCN

Many observations have demonstrated that the circadian pacemaker can be phase shifted and reset. In animals and humans these phenomena typically do not take place instantaneously but require from a few days to one week in order to completely shift the clock to a new phase. The speed is dependent on the direction of the shift and how large the shift is. As a general rule, phase delays occur more rapidly than phase advances.

Because SCN properties can easily be studied *in vitro*, there is now detailed knowledge about effects of phase-shifting agents on the SCN rhythm. One way to accurately determine the phase of the SCN rhythm is to record spontaneous electrical activity in SCN neurons, which is typically increased during the mid-subjective day as compared with subjective night [65, 82–84]. This technique has been widely used in many studies, and from these reports a complicated model of rhythm entrainment in mammals has slowly evolved, involving a number of pathways, neuromodulators, and transmitters. Light is the primary synchronizing signal to the SCN. Photoc information is conveyed principally to the ventrolateral (VL), also named “core,” region of the SCN by glutamatergic input via the retinohypothalamic tract (RHT), a group of axons within the optic nerve that originate from a restricted group of retinal ganglion cells and project directly to the VL SCN [85, 86]. Nonphotic input also reaches the VL SCN via neuropeptide Y (NPY) and γ -aminobutyric acid (GABA) in the geniculohypothalamic tract (GHT) and the intergeniculate leaflet (IGL) of the lateral geniculate nucleus (LGN) and serotonin from the median raphe nucleus [87]. According to the current model of mammalian entrainment, activation of photoreceptors in the rodent retina causes glutamate release from SCN terminals of the RHT [88]. In retinorecipient SCN neurons glutamate release causes depolarization, Ca^{2+} influx, and Ca^{2+} -activated cAMP response binding element

(CREB)-dependent activation of clock genes [89–92]. Pituitary adenylate cyclase-activating polypeptide (PACAP) is colocalized with glutamate in RHT terminals [93] and may be involved in photic signal transduction [94–97]. PACAP potentiates glutamate-induced phase delays during the early subjective night and blocks glutamate-induced phase advances during the late night [95]. However, the effects appear to be complex, and the exact physiological role of PACAP is not yet certain [98]. In a diurnal rodent, the degus, it has been suggested that retinal innervation also includes the inhibitory transmitter GABA, which may indicate substantial differences in photic entrainment in diurnal versus nocturnal animals [99].

As described earlier, similar to the *Bulla* retinal clock, light phase delays the SCN in early subjective night and phase advances in late subjective night. In contrast, light stimuli during the subjective day have little effect [10]. The phase-shifting responses can be mimicked with depolarizing agents. For instance, glutamate, *N*-methyl-D-aspartate (NMDA), and nitric oxide (NO) generators cause a light-resembling phase response curve (PRC) in vitro [100] and optic nerve stimulation in the SCN in vitro generates a similar PRC as light [101]. Furthermore, NMDA activation causes lightlike behavioral phase shifts [102–104]. Several studies suggest that phase delays and advances of the SCN rhythm involve a number of intracellular cascades that take place at different circadian phases [105]. During the subjective day cAMP/protein kinase A (PKA) and PACAP phase advance the SCN, but these compounds have no effect during the subjective night [94, 106, 107]. However, phase shifts during the subjective night can be generated by glutamate (light), NMDA, NO, acetylcholine, and cyclic guanosine monophosphate (cGMP) [100, 108]. Adding another level of complexity, the effect of glutamate varies within the night period. In early subjective night glutamate stimulation induces Ca^{2+} -mediated intracellular Ca^{2+} release by ryanodine receptors that cause phase delays [109]. In late subjective night, on the other hand, it has been suggested that glutamate stimulation instead would activate the guanylyl cyclase (GC)/cGMP/protein kinase G (PKG) pathway and thereby cause phase advances [110].

Photic responses can be shaped by nonphotic inputs. For instance, the well-studied transmitters 5-HT and NPY phase shift the clock during the day and also modulate photic signaling [87]. The role of 5-HT is not clear, partly because of contradictory results in different species and experimental differences in vitro versus in vivo. Several studies, however, have demonstrated that 5-HT and its agonists cause robust phase shifts in SCN brain slices during the subjective day, and it has been suggested that the serotonergic pathway is involved in light entrainment to the SCN [111]. NPY reduces light-induced and light-like phase delays and advances in vivo and in vitro [87]. The pineal hormone melatonin is another mediator of light response at dusk and dawn and has been reported to gate sensitivity in the SCN via protein kinase C [112–115]. Melatonin is released during the dark period in both nocturnal and diurnal animals. Its exact function is not known; however, there is an ongoing debate of whether melatonin consolidates sleep and might be useful for therapeutic reasons to treat circadian rhythm sleep disorders as well as jet lag and disturbed rhythmicity due to shift work. The impact of melatonin levels has also been discussed regarding psychiatric diseases. The issue is certainly interesting since melatonin may have many implications in sleep and rhythmic disorders and a large number of studies examining melatonin release in patients with major depression (MD) and seasonal affective disorder (SAD) have been performed. However, these studies have reached different conclusions, and it is yet not clear if MD and SAD can

be correlated to altered concentrations of melatonin. In photoperiodic animals such as sheep and hamster melatonin has a more well-defined role and acts by coding the reproductive season [116].

1.6 CHRONOPHARMACOLOGY

Abrupt disturbances of circadian rhythms may cause insomnia, dysphoria, loss of appetite, gastrointestinal problems, fatigue, and difficulties concentrating, typical effects observed after rapid traveling across time zones, so-called jet lag [117]. Importantly, rhythmic dysregulation and desynchrony may also appear and play a major role in development of severe disease conditions, for instance affective disorders [118] and certain cancer forms [119]. The distress caused by circadian disruption is often correlated to increased levels of glucocorticoid secretion, which may in turn feed back negatively on the circadian entrainment system [120, 121]. The organization of time appears to have major impact in certain human diseases; for instance, asthma attacks, ulcer disease, hypertension, and coronary infarction clearly follow a circadian pattern of occurrence and/or severity that needs to be considered during treatment. This has resulted in the development of *chronopharmacology*, therapy based on the theory that most physiological functions follow a circadian rhythm and suggests the importance of using chronopharmacologically adjusted treatment in practical medicine [122]. Furthermore, the common prevalence of sleep disturbances associated with circadian dysfunctions in mood disorders emphasizes the necessity to develop new preventive and therapeutic strategies with chronobiological approaches. Drug efficacy for most compounds, including antipsychotics, antidepressants, benzodiazepines, and barbiturates, follows a circadian rhythm [123]. If biorhythms can be restored or strengthened by chronobiologically administered drugs or other treatments, the individual's life quality, and perhaps even life span, can be increased.

1.6.1 Affective Disorders and Lithium

During the last decade extensive research has been conducted regarding the circadian component in unipolar and bipolar disorders. Certain symptoms (daily variation in mood, early awakenings in the morning, seasonal relapses, altered rhythm in body temperature, increased concentration of melatonin, and disturbances in the circadian release of cortisol and thyrotropin) may be associated with a fundamental dysregulation of circadian rhythms, and it has been suggested that situations that result in an alteration of circadian rhythms can be correlated to an increased risk of relapse in bipolar patients [118, 124]. If the circadian system is altered in the disease, therapeutic substances should hypothetically also exert an effect on rhythmicity. In bipolar disorder the main drug of choice is lithium. Indeed, a number of experimental studies have demonstrated that lithium does have effects on circadian rhythms in animals and humans. These effects include lengthening of circadian period, phase shifts, reduction of circadian amplitude, and changes in light sensitivity and stabilization of rhythms. This literature has grown large, but a brief summary of a large portion of the main findings will be given here.

The fact that lithium may "slow down" and impact circadian rhythms was suggested already a few decades ago [125–127]. Seggie and colleagues performed

several studies examining the effect of lithium on circadian rhythmicity and found that lithium phase shifted behavior and the rhythmic release of melatonin and other hormones, although the direction of the phase shifts differed in some studies [128, 129]. Welsh and Moore-Ede [130] demonstrated that lithium significantly lengthened the circadian period, but not amplitude, of perch hopping in squirrel monkeys in a dose-dependent fashion. It should be mentioned that the primate study was performed in constant light, not darkness. Importantly, long-term constant light desynchronizes the circadian rhythm in mice and may therefore have major impact on studies of circadian rhythms [131]. In our laboratory we used the *Bulla* mollusk model to study the effect of chronic lithium chloride on the spontaneous firing rhythm in the *Bulla* clock neurons and found that the period was lengthened by lithium in a concentration-dependent fashion, an effect that was enhanced by light [132]. Furthermore, lithium pulses in combination with depolarizing K^+ pulses significantly phase delayed the pacemaker. Our group also showed that lithium similarly lengthens the period in cultured mouse SCN neurons [133], and recently it was reported that mouse locomotor activity rhythms also are lengthened by lithium [134]. LeSauter and Silver [135] showed that lithium also lengthened the circadian activity period in lesioned hamsters with SCN grafts. Hafen and Wollnik [136] studied the effect of lithium in three different rat strains that showed altered circadian activity patterns. The investigators found that lithium caused a period lengthening as well as a decrease in amplitude and general reduction of the activity rhythm. The authors therefore discussed the possibility that decreased activity would feed back on the circadian period and the effect of lithium would therefore not be primary. The authors' findings did not support this theory because they could only find a significant correlation between activity level and period lengthening in one of the rat strains. The authors therefore concluded that their results strengthened the hypothesis that lithium acts pharmacologically on the pacemaker system and that the observed effects were not secondary to a feedback from the reduced overall activity level. However, a secondary effect due to negative side effects and activity feedback on the pacemaker could not be completely excluded. Klemfuss and Kripke [137] found that lithium stabilizes circadian rhythms in hamster. Similar to McEachron et al. [125], Subramanian et al. [138] studied lithium effects on biochemical parameters in Wistar rats. Chronic lithium treatment delayed rhythms in glucose, Ca^{2+} , and K^+ but advanced the rhythms in malondialdehyde, cholesterol, and lactic acid. McEachron et al. [125] also found both delays and advances of biochemical rhythms, where 8 of 11 parameters were delayed and 3 of 11 were advanced. As an explanation the authors suggested that biochemical rhythms are linked with two different oscillators that are differently affected by lithium. In chick pineal gland, lithium produced two peaks of melatonin secretion in which one of them was delayed as compared with the single control peak [138a], and lithium has a lengthening effect of the period in *Drosophila* maintained in constant darkness [139]. Although secondary effects due to side effects and activity feedback cannot be completely excluded, the studies described so far strongly suggest that lithium in most species lengthens and may stabilize circadian period in experimental animals, possibly by influencing glycogen synthase kinase-3 in the master pacemaker [134, 139]. However, a slightly different conclusion was reached in a paper by Williams and Jope [140]. The authors studied the transcription factor activator protein 1 (AP-1) DNA binding activity in rat cerebral cortex stimulated by a cholinergic agonist and

found that stimulated AP-1 binding was influenced by a circadian rhythm. When chronic, but not acute, lithium administration was administered, however, this circadian component was abolished. Although this study did not support the stabilizing effect of lithium on circadian rhythms, it was not determined whether the effect was caused by a direct effect of lithium on the circadian rhythm or if the effect was indirect via inhibition of signaling immediate early gene pathways involved in AP-1 activity, which in turn could influence the circadian clock.

In humans, lithium also appears to have a lengthening effect of the circadian period in both healthy individuals and patients with bipolar disorder and major depression and may even work as a prophylactic [141, 142]. It has also been reported that lithium enhances chronobiological treatments such as sleep phase advances in bipolar patients [143].

The mechanism of lithium may involve modulation of intracellular and extracellular ion concentrations. Lithium depolarizes neurons and modulates the concentration of potassium in the brain, possibly by blocking potassium channels and inhibiting the Na^+/K^+ adenosine triphosphatase (ATPase) [144–146]. Interestingly, recent studies strongly suggest that ionic membrane conductances such as K^+ and Ca^{2+} may be involved in the intracellular circadian machinery [71, 147–149]. Lithium may therefore impact the circadian clock directly by modulating membrane potential and K^+ flux.

In summary, a large pool of data suggests that lithium does affect circadian rhythms to some extent, possibly by influencing the circadian clock and lengthening and stabilizing the circadian period. However, this statement still needs to be acknowledged with some caution because the nature of the circadian effects is not fully consistent between studies.

1.6.2 Antidepressants and Effects on Sleep

Many antidepressants affect the sleep architecture. Both negative and positive effects on sleep structure have been reported [150]. Whether these effects are circadian or impact the homeostatic sleep circuits has not been determined. Nevertheless, the circadian system and the sleep circuits are interacting and drugs may impact both systems simultaneously. In a study performed in rats, the selective serotonin reuptake inhibitor (SSRI) zimeldine initially increased wakefulness, followed by an increase in slow wave sleep (SWS) stage 2. Rapid-eye-movement (REM) sleep was abolished after zimeldine treatment. The authors also administered L-tryptophan, which decreased waking and increased SWS when administered in late, but not early, light phase, clearly demonstrating the impact of circadian drug sensitivity to L-tryptophan [151]. The drug fluoxetine had similar effects in Syrian hamsters in which REM sleep was significantly decreased and non-REM sleep was increased [152]. In addition, the drug decreased brain temperature. A partial tolerance to the reduction of REM sleep, but not decreased hypothalamic temperature, was developed during chronic administration of the drug. In humans, Silvestri et al. [153] administered the SSRIs paroxetine and fluvoxamine to healthy subjects and performed electroencephalographic (EEG) recordings. Both drugs disrupted the sleep pattern, paroxetine more so than fluvoxamine, and paroxetine-induced sleep disruption that persisted into the withdrawal phase. Sleep disruption and decreased sleep quality caused by another SSRI, fluoxetine, in depressed children was also demonstrated by Armitage et al. [154].

However, in contrast to earlier studies in adult subjects investigating fluoxetine's effect on sleep [154–156], Armitage et al. did not find that fluoxetine reduced REM sleep in children [154]. Nefazodone, on the other hand, had an improving effect on sleep quality [154].

A different result with paroxetine was obtained by Schlösser et al. [157]. In their subjects, paroxetine administration did not alter sleep efficiency, total sleep time, sleep onset latency, number of awakenings, and awake during sleep period times. However, in accordance with Silvestri et al. [153], paroxetine medication affected REM sleep (prolonged REM latency and a decrease in the number of REM phases). The same group investigated the effect on hormones at night and profiles were obtained for prolactin, growth hormone (GH), cortisol, corticotropin (ACTH), luteinizing hormone (LH), testosterone, and melatonin [158]. None of the hormonal profiles were significantly altered by paroxetine; however, fluoxetine hydrochloride increased the circadian amplitude in prolactin release in postmenopausal women [159]. Differences in the experimental protocols may explain the contradictory results regarding sleep architecture. Different doses of the drug (20 vs. 30 mg/day) were used, but more significantly, the time of administration differed between the studies. Silvestri et al. [153] administered the drug morning and evening whereas Schlösser et al. [158] gave the drug only in the morning to the subjects. Because the serotonin levels are normally high during the subjective day, the morning-only protocol may have produced less side effects due to an already increased concentration of 5-HT and therefore also did not affect the sleep pattern significantly. Not in accordance with this hypothesis is a study by Saletu et al. [158], who compared SSRI administration given in the morning versus the evening. Total sleep time and sleep efficiency deteriorated under both morning and evening dosing and nocturnal wake time and sleep stage 1 increased. However, a delayed sleep onset and REM latency was lengthened only after the morning intake.

Whether differences in the experimental protocols explain the opposite results or not, these results clearly demonstrate the importance of drug concentration and timing of drug administration not only in pharmacological therapy but also in experimental studies in order to compare obtained results between different drugs and studies.

1.6.3 Antidepressants and Circadian Rhythms

Because of the unclear role of 5-HT in the circadian system it is also difficult to interpret effects of SSRIs on circadian rhythms, and studies have reached different conclusions. However, there is no doubt that antidepressants exert major impacts on circadian rhythms, including change of period, phase, and entrainment. A few of them will be discussed here. Many studies have suggested that 5-HT modulates photic responses in the SCN [160]. Certain 5-HT-enhancing antidepressants attenuate phase shifts [161]. However, a different conclusion was reached by Moriya et al. [162], who found that 5-{3-[(25)-1,4-benzodioxan-2-ylmethyl] amino} propoxy}-1,3-benzodioxole HCl (MKC-242), a selective 5-HT (1A) receptor agonist, accelerated the reentrainment of hamster wheel-running rhythms after 8-h phase shifts and produced larger phase advances of the wheel-running rhythm produced by light pulses. Furthermore, the authors found that MKC-242 increased light-induced *Per1* and *Per2* mRNA expression in the mouse SCN and suggested this as a molecular

mechanism underlying the potentiated phase shifts [163]. However, a direct link between increased expression of *Per* and magnitude of phase shifts remains to be clarified, although it has been demonstrated that light exposure causes induction of *Per1* [164] and photic phase delays can be inhibited by *Per1* and *Per2* antisense oligonucleotides [165, 166]. The drugs 8-hydroxydipropylaminotetralin, paroxetine, buspirone, and diazepam did not have any significant effects on *Per* expression [163].

A study of circadian wheel-running activity after antidepressant administration was performed in rats [167]. Wheel-running activity rhythms were recorded in three inbred strains of laboratory rats in constant darkness, among which two of these strains showed abnormal multimodal circadian activity patterns. Chronic treatment with moclobemide, a reversible and selective monoamine oxidase (MAO) type A inhibitor, and desipramine, a preferential norepinephrine reuptake inhibitor, but not the SSRIs clomipramine and fluoxetine administered ad lib, consistently increased the circadian amplitude of the activity rhythm, and the abnormal bimodal activity pattern in one of the strains became unimodal. Furthermore, the free-running period was shortened by moclobemide and desipramine, an effect that persisted for a long time after treatment (aftereffects). Fluoxetine, however, which did not exert any effect in this study, suppressed food intake in a dose-dependent fashion during early night but not during mid and late night [168]. Although the studies measuring locomotor activity and food intake are not directly comparable, they demonstrated inconsistent results of fluoxetine on different kinds of rodent behavior. Differences in the experimental protocol such as time of drug administration may be one explanation. Another compound, the α adrenoceptor agonist clonidine, shortened the period and amplitude of circadian activity rhythms in constant conditions [169].

The effect on circadian cortisol release has also been under investigation because hyperactivation of the hypothalamic–pituitary–adrenal (HPA) axis is associated with major depression and may also involve abnormal circadian rhythmicity of cortisol levels [170]. Linkowski et al. [171] found that electroconvulsive therapy or amitriptyline restored hypersecretion of cortisol to control concentrations and the timing of the cortisol nadir (earlier in depressed patients before treatment) was normalized. Steiger et al. [172] reported that cortisol levels were returned to normal after treatment with tricyclic antidepressants (amitriptyline and imipramine) but secretion of growth hormone and altered EEG pattern remained disturbed in depressed subjects. In contrast, Rota et al. [173] found a positive effect of fluvoxamine and amitriptyline on the abnormal cortisol rhythm in patients with major depressive disorder, but this effect was not significant. From the report it is not clear when the drugs were administered. However, the lack of effect may not be related only to circadian parameters but may be due to nonresponsiveness caused by an activated HPA axis [174]. In rats Reul et al. [175] found that amitriptyline attenuated basal cortisol levels and Gomez et al. [176] demonstrated that phenelzine and imipramine altered the normal circadian pattern of corticosterone; however the circadian amplitude was reduced by the treatment, not enhanced. The experimental protocols differed in terms of drug administration; Reul et al. [175] administered antidepressants in the drinking water whereas Gomez and collaborators [176] administered once a day in the morning by injection.

The discrepancies between the above-discussed studies describe a large complexity of different antidepressant drugs and their effects on sleep and circadian rhythms. Certain antidepressants may themselves cause circadian rhythm sleep disorders,

manifested as sleep disturbances, day somnolence, and fatigue. These symptoms are commonly treated with benzodiazepines or other sleep-promoting substances. For instance, in one study by Hermesh and co-workers [177] fluvoxamine but not the other SSRIs fluoxetine and clomipramine caused circadian rhythm sleep disorder. From these studies it is impossible to draw one specific conclusion of how antidepressants, as one general group of compounds, affect the circadian system. It is clear, though, that the time of administration of several antidepressant drugs appears to be important in terms of drug efficacy and side effects such as sleep disorganization, which in turn suggests that many of these compounds may be powerful *zeitgebers* (“timegivers”) acting on the circadian pacemaker via the neurotransmitter systems in the brain. The impact on phase by these substances may be enhanced by classical *zeitgebers* such as light; for instance, light therapy given in the morning (giving a 2-h phase advance in each individual) during two weeks in combination with citalopram significantly improved the effect of the antidepressant drug in patients with MD and bipolar disorder compared to placebo [178]. Furthermore light therapy is an effective treatment in SAD [179]. Whatever the underlying mechanism of light therapy is, these and other reports again emphasize the importance of strengthening the circadian system as a powerful tool to improve neuropharmacological treatments. Chronobiological treatments and life-style strategies may also have a preventive and prophylactic effect on the reoccurrence of psychiatric disorders [180].

1.6.4 Benzodiazepines

It was discovered early that benzodiazepines could phase shift circadian rhythms in rodents, primates, and humans [181]. These effects may be mediated by the serotonergic system [182, 183]. It has also been suggested that triazolam facilitates phase shifts and would therefore help in adjusting to new time environments and attenuate jet lag and shift work effects [184]. However, facilitation of reentrainment by triazolam could not be demonstrated in squirrel monkeys [185]. Again, the timing of drug administration is crucial for reaching maximum beneficial effects [184] and benzodiazepines may cause both advances and delays depending on when during the circadian cycle they are administered. It has also been demonstrated that locomotor activity may be required for benzodiazepine-induced phase shifting in hamsters. Van Reeth and Turek [181] found that when hamsters were immobilized, triazolam- (which does not have a sedative effect in these animals) induced phase advances and delays were inhibited. In one study of healthy subjects benzodiazepines reduced the melatonin levels and altered the rhythmic profile of the hormonal release [186]. The mechanisms may involve GABA_A receptors because it was found that flunitrazepam increases the duration of spontaneous GABAergic postsynaptic currents and potentiates the amplitude of GABA evoked currents in rat brain slices of the SCN [187]. The effect of diazepam and triazolam on clock gene expression was investigated in the mouse cerebellum. The benzodiazepines acutely reduced *Per1* messenger RNA (mRNA) level when injected at *zeitgeber* time (ZT; time in hours after light goes on) 4 and 16 but the effect was transient [188]. Vansteensel et al. [189] pointed out another level of complexity of the phase-shifting effects of non photic stimuli like benzodiazepines: Midazolam and the opioid receptor agonist fentanyl induced phase advances of *activity onset* but not *activity offset* when given

mid- to late subjective day in hamsters. Finally, Subramanian and Subbaraj [190] found that when diazepam was given in the drinking water to mice, the free-running period was either shortened or lengthened and phase shifts introduced during the end of the circadian cycle were attenuated in the treated animals. Nevertheless, benzodiazepines clearly can shift circadian rhythms in humans and experimental animals. If used wisely, these compounds may be helpful in overcoming negative phase-shifting effects such as jet lag but also have negative effects if used at the “wrong” time. Interestingly, in an early study by Okawa et al. [191], a blind child was entrained for several years by administration of nitrazepam. More specifically designed studies on benzodiazepine effects on phase shifting in real life, however, are necessary in order to determine exactly how these drugs should be used in this context.

1.6.5 Inflammatory Molecules

Disturbances in biological rhythms, especially the sleep–wake cycle, not only are associated with psychiatric mood disorders but also involve numerous physical and cognitive disorders. Such disturbances may be brought about by infectious diseases, autoimmune disorders, malignancies, or aging. In these conditions so-called *cytokines* are released for intercellular communication to activate or modify immune cell responses as well as cellular proliferation, maturation, and survival. There is now accumulating evidence that cytokines can also operate at the tissue or systems level in influencing the mammalian central nervous system. A number of cytokines have been ascribed somnogenic properties [192], but recent observations suggest that cytokines also are involved in mediating a number of physiological impairments via their effect on the circadian timing system. Because of their great impact during common infections and a number of inflammatory conditions, we will review what is known so far about cytokines and circadian rhythms.

Cytokines are small secreted proteins that exhibit autocrine or paracrine actions to regulate the intensity and duration of immune responses. They stimulate the activation, proliferation, or differentiation of cells involved in the defense against microbial invasion of an organism. There are proinflammatory cytokines, for instance interleukin (IL) 1, tumor necrosis factor (TNF) α , and interferon (IFN) γ that amplify inflammatory reactions, and anti-inflammatory cytokines, such as IL-4, IL-6, and IL-10 that are involved in the reduction of proinflammatory reactions [193]. Although first identified in the immune system, cytokines can be produced by glial cells and affect functions in the brain.

1.6.6 Cytokines and Disturbances in Circadian Sleep–Wake Rhythms

Cytokines and microbial products released during an infection and/or immune activation cause physiological and psychological effects that are collectively termed *sickness behavior*, characterized by anorexia, depressive symptoms, muscle aches, somnolence, and lethargy [194]. Proinflammatory cytokines, in particular IL-1 and TNF- α , are well known for being somnogenic and microbial products such as lipopolysaccharide (LPS) exert their effects in this respect by being potent inducers of these cytokines. Increased cytokine release occurs during aging and in age-related neurodegenerative diseases such as Alzheimer’s disease and Parkinson’s disease.

During these conditions nocturnal disruptions of sleep, manifested as agitation during nighttime, and increased number of sleep episodes during the day are common [195–198]. Patients with cancer and multiple sclerosis (MS), diseases that also are associated with elevated cytokine release, may also show severe disturbances in the sleep–wake architecture and altered rest–activity patterns [199–201]. Patients with cancer and MS often suffer from MD [202–204] that could contribute to the sleep disturbances. In developing countries in sub-Saharan Africa the infectious disorder sleeping sickness [human African trypanosomiasis (HAT)] is reemerging. The disease is caused by infection with the extracellular parasite *Trypanosoma brucei* that results in immune activation and early release of the proinflammatory cytokines IFN- γ and TNF- α [205]. Severe fragmentation of the sleep–wake rhythm characterizes the disease, which increases progressively during the course of disease [206, 207]. Similar disruptions in the sleep patterns occur in rodents experimentally infected with the parasites, and trypanosome-infected animals therefore provide a model to study pathogenic mechanisms underlying disturbances in sleep pattern and rhythms [208].

In patients afflicted with these conditions, but also in subpopulations of aging individuals, increased concentrations of cytokines have been found in plasma, cerebrospinal fluid (CSF) and/or brain. Considering the proinflammatory cytokines, patients with Alzheimer's disease exhibit elevated concentrations of IL-1, IL-6, and TNF- α [209, 210], and in a rodent model of this disease increased levels of IL-1, TNF- α , and IFN- γ have been found [211]. Increased levels of circulating IL-1, IL-6, TNF- α , and IFN- γ have been associated with MD [212, 213]. Similarly, increased concentrations of IL-1, IL-6, TNF- α , and IFN- γ have been found in subpopulations of elderly humans as well as in old mice and rats [214–219]. In sleeping sickness patients, and in experimental rodent models of African trypanosomiasis, there is marked increase of IL-1, IL-2, IL-4, IL-10, TNF- α , and IFN- γ in the central nervous system [220, 221]. A positive correlation between plasma levels of IFN- γ and the severity of the disease has been demonstrated by Radomski et al. [222]. In spite of the fact that somnogenic proinflammatory cytokines such as IL-1 and TNF- α are released in both aged individuals and patients affected with these diseases, with the exception of certain forms of MD, there is usually no hypersomnia. Rather, a common feature appears to be a disruption of the sleep–wake pattern, pointing to an alteration not only in the sleep circuits but also in the circadian system.

Direct evidence for linking cytokines to disturbances in sleep and perhaps circadian rhythms in humans has been obtained from studies on patients with MS and certain forms of cancer undergoing intensive immunotherapies. IFN- γ , IL-2, and TNF- α can cause MD that may include sleep and circadian rhythm disturbances [124, 223, 224]. Conversely, it has been suggested that certain patients suffering from depression may have a “chronic inflammation” and reducing inflammation could offer a way to treat such disorders [212].

Recent experimental data investigating more directly effects of cytokines on circadian parameters suggest that some of these molecules may be potent modulators of circadian clock functions. In the rat brain, the receptor for IFN- γ is located in the ventrolateral part of the SCN and in areas such as the piriform and entorhinal cortex, midline thalamus, medial hypothalamus, and tubero-mammillary nuclei [225]. When rats were entrained in a 12:12 h LD cycle, but not in free-running conditions, the receptor expression in the SCN was low during the subjective day and increased

during the early subjective night, with the highest expression at ZT 15 [226, 227]. Other data also point out an influence of IFN- γ on the circadian timing system. For example, IFN- γ administered subcutaneously in mice at ZT 12, but not at ZT 0, caused a marked reduction of the mRNA levels of *per* in the SCN [228] and intracerebroventricular injections of IFN- γ alters locomotor activity in golden hamsters [229]. IFN- γ operates in synergy with TNF- α [230], which in fact was first isolated from rabbits infected with trypanosomes under the name of cachectin. IFN- γ and TNF- α in combination with bacterial LPS blunted the spontaneous firing activity and reduced spontaneous excitatory postsynaptic activity in slices of the SCN [231]. Furthermore, we have recently found that IFN- γ decreases GABAergic synaptic activity and modulates decreases impulse pattern in dispersed SCN neurons [232]. Bacterial LPS phase shifts activity rhythms in mice during early subjective night, similar to photic signals [233]. Another proinflammatory cytokine, IFN- α , has also been demonstrated to have a major impact on clock functions. In a study by Koyanagi and Ohdo [234] IFN- α blunted rhythmic expression of CLOCK and BMAL1, rhythmic behavioral activity, and rhythmic release of vasopressin. Taken together, the recently accumulating number of studies examining cytokine effects on brain function strongly suggest that cytokines alter not only sleep functions but also SCN physiology and circadian output both in vitro and in vivo.

1.7 CONCLUDING REMARKS

Circadian rhythms are fundamental processes in most organisms which in humans appear to have major impact on physiological processes, life quality, and well-being. This has become more apparent during the last few decades when development of a high-technology and high-efficiency society has resulted in more artificial life environments, such as shift work and frequent business traveling across time zones, as well as increased stress levels resulting in sleep and rhythm dysfunctions. In addition, more advanced pharmacological therapies now available in the clinics have pushed the development of sophisticated therapeutics to involve chronopharmacological strategies as powerful tools to optimize drug effects and minimize toxic side effects of compounds used for a number of diseases, including psychiatric disorders, infectious diseases, inflammatory conditions, autoimmune disorders, and neurodegenerative diseases. With the increasing average life span of humans in Western society, circadian rhythm disorders associated with aging have also attracted more attention and focus for chronobiologists. In other words, circadian rhythm disorders are phenomena belonging to modern society and the life style that is associated with modern environments.

The master clock in the hypothalamus is a remarkable structure with a well-defined biological function: the generation and maintenance of an internal timing program in the body which can be severely disrupted by neurotransmitters, hormones, pharmacological compounds, and immune system mediators, resulting in substantial negative effects on physiological functions. Although not reviewed here, commonly used drugs as caffeine [235], nicotine [236], and alcohol [237] may also influence circadian parameters and change period, amplitude, and entraining properties. Rhythmic disturbances may play a role in linking certain conditions to others; for instance, alcohol intake may alter rhythms and alcoholism is commonly associated with major

depression, which in turn is characterized by sleep and rhythm alterations. The circadian aspect may in this context have an unforeseen role in that strengthening the timing machinery could improve the outcome of treatment of these disorders and others. Finally, the importance of maintaining the circadian program as intact as possible has also become evident in development of tumors [238–240], and circadian clock function is important for the cell cycle, DNA damage response, and tumor suppression in vivo [241]. Studies of circadian rhythms and circadian clock functions have entered a new era of research and reached a higher level of importance, perhaps even greater than the original pioneers in the field ever could imagine.

2.1 INTRODUCTION

The hormone of darkness melatonin (*N*-acetyl-5-methoxytryptamine) is released by the pineal gland in a circadian fashion defining the length of the night and relaying photoperiodic information to the organism [1]. Pineal melatonin provides circadian

and seasonal timing cues for the regulation of prolactin secretion, color coat, and reproduction in seasonal breeders [2–7]. Furthermore endogenous melatonin promotes sleep [8], fine tunes phase position and amplitude of circadian rhythms [9], and participates in the regulation of neuroimmune function [10, 11] and inhibition of cancer tumor cell growth [12]. Locally released melatonin modulates dopaminergic transmission in retina and participates in the transmission of visual and circadian information to the brain [13, 14]. Exogenous melatonin through activation of melatonin receptors in the central nervous system modulates a myriad of physiological functions, including sleep [15–18], circadian rhythms [18–20], and visual [21], cerebrovascular [22], neuroendocrine [23, 24], and neuroimmune [11] functions. This review will describe the cellular and signaling mechanisms by which activation of MT₁ and MT₂ melatonin receptors in the central nervous system could be involved in the treatment of insomnia, circadian rhythm disturbances, and neuropsychiatric disorders.

2.2 HISTORICAL PERSPECTIVE

Melatonin is synthesized in the pineal gland of all vertebrate species, including humans. The biological activity of melatonin dates back to 1917 when McCord and Allan (1917) discovered the blanching effects of bovine pineal extracts on tadpole skin. This bioassay was used by Lerner et al. (1959) [25] to isolate melatonin from pineal extracts and to unravel its chemical structure. The property of melatonin to aggregate pigment granules (melanosomes) in amphibian dermal melanophores was critical to demonstrate for the first time the presence of functional melatonin receptors, the structure–activity relationship of melatonin-like ligands, the coupling of melatonin receptors to pertussis toxin–sensitive G proteins, and the cloning of the first complementary DNA (cDNA) encoding a seven-transmembrane domain melatonin receptor (Mel1c) [26–28].

Aaron Lerner discovered melatonin and was the first to report its ability to induce sleepiness during the day in humans [29, 30]. This observation was followed by reports demonstrating a direct effect of melatonin on sleep processes in humans using physiological (0.3-mg) to suprapharmacological (85-mg) doses [17, 31–35]. The role of melatonin in the treatment of circadian rhythm disorders followed the publications by Redman and colleagues [36] demonstrating melatonin-mediated entrainment of free-running activity rhythms of rats kept in constant dark and by Murakami et al. [37] reporting that melatonin implants near the suprachiasmatic nucleus (SCN) accelerated reentrainment of cortisol rhythms. These pioneer studies on melatonin-induced sleep and phase shift of circadian rhythms prompted the search for melatonin receptor ligands to treat circadian and not-circadian sleep disturbances in humans (for a review see [17, 18]).

Melatonin receptor activation appears to modulate serotonin (5-HT) receptor–mediated signaling in the brain. Small doses of melatonin delivered into the rat nucleus accumbens decrease locomotor activity and rearing and increase grooming and sniffing behavior [38]. These behavioral effects are counteracted by 5-HT agonists and tricyclic antidepressants but not by dopamine antagonists, suggesting an interaction between 5-HT and melatonin receptor–mediated signaling in the nucleus accumbens [38]. Melatonin, as demonstrated for 5-HT_{1A} agonists and

antidepressants, inhibited 5-HT_{2A} receptor-mediated headshakes and stimulation of phosphoinositide hydrolysis in rat cortical slices through a receptor-mediated mechanism [39]. Melatonin administered in vivo reduced 5-HT_{2A} receptor agonist-induced increase in phosphoinositide hydrolysis without affecting receptor density, further supporting the interaction of the melatonin and 5-HT systems. Melatonin also modulates the sensitivity of 5-HT₂ receptor-mediated sleep responses in the rat [40]. More recently, the discovery that agomelatine, an agonist for MT₁ and MT₂ receptors and antagonist at 5-HT_{2C} and 5-HT_{2B} receptors, is an effective antidepressant has revived the interest in the potential interactions between heterologous regulation of 5-HT and melatonin receptor signaling [41].

Concurrent biochemical, molecular, and pharmacological studies localized and established the function of melatonin receptors in the mammalian central nervous system. The discovery of functional melatonin receptors inhibiting dopamine release in rabbit retina together with the report of the structure-activity relationships for melatonin ligands [13, 42] led to the design and synthesis of the first competitive melatonin receptor antagonist, luzindole (*luz*: Spanish for “light”; *indole*: basic chemical structure of melatonin). Luzindole (2-benzyl-*N*-acetyltryptamine) was designed to mimic light signals by blocking the effects of melatonin, the hormone of darkness.

The development of 2-[¹²⁵I]iodomelatonin as a high-affinity radioligand [43–45] allowed the localization and pharmacological characterization of melatonin receptors in mammalian retina, brain, and peripheral tissues as well as the cloning of the first nonmammalian melatonin receptor (for a review see [46–49]). The cDNA encoding the *Mel1c* melatonin receptor was cloned by expression of purified messenger RNA (mRNA) from *Xenopus laevis* melanophores into mammalian cells in culture following detection by receptor autoradiography with 2-[¹²⁵I]iodomelatonin [28]. This landmark discovery led to the cloning of the mammalian melatonin receptors *Mel1a* and *Mel1b*, belonging to a novel subfamily of seven-transmembrane-domain G-protein-coupled receptors (GPCRs) [50, 51]. These melatonin receptors, currently referred to as MT₁ and MT₂, respectively, exhibit distinct molecular and pharmacological characteristics and are localized to different chromosomes (MT₁, 4q35.1; MT₂, 11q21–q22) [19, 52–54]. The pharmacological characterization of the mammalian MT₁ and MT₂ melatonin receptors has advanced the discovery of selective and specific ligands for these receptors [52, 55–59]. The introduction of two prototype competitive melatonin receptor antagonists luzindole and 4P-PDOT (4-phenyl-2-acetamido tetraline) [52, 60] and of mice with genetic deletion of MT₁ and/or MT₂ melatonin receptors [61, 62] allowed the functional characterization of melatonin-mediated responses in native tissues. The mammalian MT₁ and/or MT₂ G-protein-coupled melatonin receptors are viewed as potential targets for the development of melatonin receptor ligands to treat disorders involving alterations in sleep and in the phase of circadian rhythms as those observed in subjects with depression, blindness, and delay sleep phase syndrome or following rapid changes in the light–dark cycle as occur during jet travel and shift work [18, 63]. The role of melatonin receptors in the regulation of physiological functions outside the central nervous system has been recently reviewed elsewhere [22, 49].

The putative MT₃ melatonin site binds 2-[¹²⁵I]iodomelatonin with nanomolar affinity and displays a distinct pharmacological profile from other melatonin

receptors (i.e., affinity profile for MT₃ is *N*-acetylserotonin ≥ melatonin » serotonin and for MT₁ and MT₂ is melatonin » *N*-acetylserotonin » serotonin) [48, 53, 64]. 5-MCA-NAT (5-methoxycarbonylamino-*N*-acetyltryptamine), prazosin, and *N*-acetyltryptamine are selective ligands for the MT₃ site [64]. The MT₃ melatonin binding site was originally thought to be a GPCR [65, 66]. However, a protein isolated from hamster kidney and identified as quinone reductase II binds 2-[¹²⁵I]iodomelatonin and the selective MT₃ ligand 2-[¹²⁵I]-MCA-NAT with the same pharmacological profile described for the MT₃ site in both hamster brain and kidney membranes [67, 68]. The MT₃ binding site is absent in brain and kidney membranes from mice with genetic deletion of quinone reductase II [68, 69]. The complete identity of MT₃ membrane binding sites with quinone reductase II as well as the physiological relevance of these sites remains to be determined.

2.3 MELATONIN PRODUCTION

In mammals, melatonin is synthesized primarily by the pineal gland and the retina and is released in a circadian fashion with high levels during the night. The synthesis of melatonin in the pineal gland is regulated by the master biological clock, the SCN of the hypothalamus, via multisynaptic neuronal pathways and/or neurochemical transmission. Signals of dark and light are transmitted from the retina to the SCN via the retinohypothalamic tract (Fig. 2.1a). The SCN regulates the circadian production of melatonin in the pineal gland by transmitting neuronal signals through the paraventricular nucleus (PVN) of the hypothalamus, the intermediolateral (IM) cell column, and the superior cervical ganglia (SCG) (Fig. 2.1; for a review see [20, 70, 71] (Fig. 2.1a). A clock mechanism within the retina itself drives the melatonin rhythm in this tissue [14, 20]. The circadian clocks in the SCN and retina are entrained to a 24-h period by environmental light, which is sensed by the retina and is conveyed to the SCN via the retinohypothalamic tract.

Melatonin is synthesized from 5-HT through two enzymatic steps (Fig. 2.1b). First, the rate-limiting enzyme serotonin *N*-acetyltransferase (arylalkylamine *N*-acetyltransferase; AA-NAT) acetylates 5-HT to yield *N*-acetylserotonin (NAS). The second step involves transfer of a methyl group from *S*-adenosylmethionine to the 5-hydroxy group of *N*-acetylserotonin via the enzyme hydroxyindole-*O*-methyl transferase (HIOMT) [70, 72] (Fig. 2.1b). Interestingly, 5-HT levels in the pineal gland follow a triphasic pattern with constant levels during the day, a sharp increase at lights off, and a concomitant decline as the levels of melatonin increase [73]. Transcriptional and posttranscriptional mechanisms regulate the daily rhythms of AA-NAT [20, 70, 74–76] and HIOMT [77] activity. Circadian melatonin secretion from the pineal gland shows the acrophase during the dark period and a nadir during the light phase in both diurnal and nocturnal species [18]. Light exposure during the dark phase suppresses melatonin production [78]. In animals as well as in humans maintained under the adequate photoperiod, the duration of melatonin secretion is longer during the winter nights and shorter during the summer nights, which may contribute to differential seasonal responses mediated by endogenous melatonin [78]. Low levels of AA-NAT and HIOMT have been also detected in brain and peripheral tissues (spinal cord, raphe nucleus, striatum, gut, testis), suggesting melatonin synthesis in these tissues [79].

Figure 2.1 Regulation of melatonin synthesis. Melatonin is synthesized in the retina and in the pineal gland. In the pineal gland, melatonin synthesis follows a rhythm driven by the SCN, the master biological clock, following a multisynaptic path, including, among others, the SCG. Norepinephrine released from postganglionic fibers activates α_1 and β_1 adrenoreceptors in the pinealocyte, leading to increases in second messengers [i.e., cyclic adenosine monophosphate (cAMP) and inositol trisphosphate] and in the activity of AA-NAT, the rate-limiting step in melatonin synthesis. The system is dramatically inhibited by light, the external cue that allows entrainment to the environmental light–dark cycle. The photic signal received by the retina is transmitted to the SCN via the retinohypothalamic tract, which originates in a subset of retinal ganglion cells. The pineal melatonin thus serves as the internal signal that relays day length, allowing regulation of seasonal changes in reproductive physiology and behavior. The pars tuberalis of the pituitary gland interprets this rhythmic signal and generates a precise cycle of expression of circadian genes. Melatonin synthesis in the photoreceptors of the retina follows a similar daily rhythm that is generated by local oscillators. (Reprinted from [71] with permission from Elsevier.)

2.4 MELATONIN RECEPTORS

2.4.1 Molecular Structure

In mammals, melatonin activates at least two high-affinity G-protein-coupled membrane receptors—the MT_1 and the MT_2 —that mediate a myriad of functional responses [19, 47]. The best-characterized signaling pathways for the mammalian MT_1 and MT_2 melatonin receptors is through coupling to heterotrimeric G proteins ($G\alpha\beta\gamma$) and dissociation into $G\alpha$ and $G\beta\gamma$ dimers that interact with effector molecules involved in the transmission of cell signaling. The MT_1 and MT_2 melatonin receptors show distinct molecular structure, pharmacological profile, and chromosomal localization [52, 54, 80]. The molecular structure consists of seven transmembrane (TM) helices (I–VII) linked by three alternating intracellular and extracellular loops. Melatonin receptors are a distinct group within the family of GPCRs having an NRY motif rather than a DRY or ERY motif that is present in intracellular loop II of all other GPCRs [50]. Mutation of the Asn124 in the NRY motif of the MT_1 melatonin receptor indicated that this amino acid regulates cAMP signaling, calcium channel activity, and receptor trafficking [81]. Furthermore, in the

MT₁ melatonin receptor the conserved cysteines C127 and C130, localized at the end of transmembrane domain III, are needed for normal G-protein activation and receptor trafficking [82]. Biochemical studies revealed sulfhydryl groups to be important for melatonin binding [83, 84]. A disulfide bond between Cys113 and Cys190 localized in extracellular loops I and II, respectively, forms an essential disulfide bond for high-affinity melatonin binding to MT₂ and possibly to MT₁ receptors as well [85]. Furthermore, using chemical modification with thiol-reducing and thiol-alkylating agents and site-directed mutagenesis, we reported that Cys140 regulates binding affinity while Cys143 and Cys219 determine binding capacity to the human melatonin MT₂ receptor [85]. In conclusion cysteines located in MT₂ receptor regions near the ligand binding site and/or G-protein coupling regions are involved in *N*-ethylmaleimide-induced changes in affinity and receptor density.

Site-directed mutagenesis revealed unique structural features within the MT₁ and MT₂ melatonin receptor molecular structure which show potentially distinct binding pockets for ligand recognition. Various models for melatonin recognition at melatonin receptors have been proposed based on the amino acid sequences of the melatonin receptor types (MT₁, MT₂, and Mel_{1c}), the helical structures of bovine rhodopsin [86] and bacteriorhodopsin [87, 88], and radioligand affinity constants (for a review see [89–92]. The conserved histidine in TM V is critical for binding to both the MT₁ and MT₂ melatonin receptors [90, 93, 94], which is in agreement with early models [86, 88]. Point mutations of conserved serines (S8 and S12) in TM III [95] and glycine G20 in TM VI [96, 97] are important for ligand binding to MT₁ receptors. In contrast, serines (S8 and S12) in TM III appear not to be involved in ligand binding to hMT₂ receptors, revealing potential structural differences between the binding pockets of the mammalian MT₁ and MT₂ melatonin receptors [90, 95]. Molecular modeling studies of the hMT₂ receptor revealed the involvement of Val204, Leu272, and Tyr298 within TM V, VI, VII, respectively as essential for ligand binding [92]. Thus, the binding pockets of the MT₁ and MT₂ melatonin receptors appear to share a common histidine residue (His7 in TM5) but also have distinct residues (Ser8 and Ser12 in TM3) necessary for ligand binding [89–91]. These differences in the molecular structure of the binding sites of the MT₁ and MT₂ melatonin receptors could be used in the design of selective and novel molecules with therapeutic potential.

2.4.2 Molecular Pharmacology

Identification and characterization of specific melatonin receptor responses in native tissues requires the use of well-characterized melatonin receptor ligands and radioligands in terms of pharmacological properties (affinity, selectivity, specificity) and ligand efficacy (agonist, competitive antagonist, partial agonist, inverse agonist) [19, 98]. This information is important as the efficacy of GPCR ligands to initiate a signaling response in target tissues is dependent on the cellular milieu, G-protein-type and/or scaffolding molecules, spare receptors, and dimer and/or heterodimer formation (for a review see [19, 99]. A ligand is considered selective on a specific receptor when its affinity and/or potency is at least 100 times higher with respect to the other receptor under consideration [53].

Prototype nonselective MT₁/MT₂ melatonin receptor ligands currently used to identify melatonin receptor-mediated responses include several agonists [e.g., 6-chloromelatonin, agomelatine (S20098)] and competitive receptor antagonists (e.g., luzindole, S20928) [52, 58, 60] (Fig. 2.2). Luzindole has 15- to 26-fold higher binding affinity for the MT₂ receptor, with an affinity constant (K_B) assessed by Schild

Figure 2.2 Chemical structures of melatonin and prototype melatonin receptor agonists and antagonists: melatonin, 5-methoxy-*N*-acetyltryptamine; 6-chloromelatonin; 6-chloro-5-methoxy-*N*-acetyltryptamine; luzindole, 2-benzyl-*N*-acetyltryptamine; 4P-PDOT, 4-phenyl-propionamide tetraline.

analysis in retina of 20 nM. The affinity constant (K_B) of luzindole to compete for melatonin-mediated vasoconstriction in caudal artery is 156 nM [52, 100]. 4P-PDOT (4-phenyl-2-propionamidotetraline) is a selective MT_2 ligand as it shows over 300 times higher binding affinity for the MT_2 than the MT_1 melatonin receptor with an affinity constant (K_B) for MT_2 melatonin receptors in retina 0.5 nM [52, 55]. Of interest is the observation that 4P-PDOT acts as a partial agonist on MT_2 melatonin receptors in the rat microcirculatory system [101] and in heterologous cells expressing recombinant receptors [90]. Luzindole and 4P-PDOT are also MT_1 melatonin receptor antagonists at 300 nM and higher concentration; however, they both act as inverse agonists in systems endowed with constitutive active MT_1 receptors [55, 102–104]. Other selective MT_2 melatonin receptor ligands characterized as competitive MT_2 receptor antagonists have been recently described [e.g. 4P-CADOT (4-phenyl-2-chloroacetamidomidotetraline), 4P-ADOT (4-phenyl-2-acetamidotetraline), K185 (*N*-butanoly-2-(5,6,7-trihydro-11-methoxybenzo[3,4]cyclohept [21a] indol-13-yl)ethanamine), GR128107 (3-(1-acetyl-3-methyl-piperidine) 5-methoxyindole, and 5-methoxyluzindole)] [52, 55, 105]. The ligand IIK7 is a selective MT_2 melatonin receptor agonist at recombinant receptors [105]. Recently, the synthesis and pharmacological characterization of S26131 [*N*-(2-{7-[3-({8-[2-acetylamin]ethyl}-2-naphthyl)oxy]propoxy}-1-naphthyl)ethyl)acetamide] which shows over 200-fold higher affinity for the MT_1 than the MT_2 melatonin receptor, was reported [57]. This molecule was synthesized by dimerization of two molecules of S20098 linked together by three methylene groups through the methoxy substituents [57]. S26131 antagonized melatonin-mediated stimulation of ^{35}S -GTP γ S [(35S)GTP γ S]; guanosine 5'-O-(3-[35S]thio)triphosphate] binding to MT_1 receptors expressed in heterologous mammalian cells with only 27 times higher affinity for the MT_1 than for the MT_2 receptor [57]. The efficacy of this putative MT_1 melatonin receptor antagonist in tissues expressing native melatonin receptors has not been reported.

GPCRs form homodimers and heterodimerize with other members of the same receptor superfamily. Oligomerization is a general phenomenon that regulates

trafficking, ligand binding, and signaling of several GPCRs, including opiate, muscarinic, α -adrenergic, and γ -aminobutyric acid (GABA) receptors [106–109]. Oligomerization and receptor internalization and/or desensitization are mechanisms by which melatonin regulates its receptors. Regulation of melatonin receptors by oligomerization is supported by several findings. First, isolation of solubilized ligand–melatonin receptor complexes by gel filtration chromatography yield molecular sizes of 110 or 150 kDa [110, 111], which corresponds to receptor trimers and tetramers, respectively, and show low affinity for 2- 125 I]iodomelatonin binding [110, 111]. Second, Ayoub et al. [112] reported constitutive dimerization and oligomerization of hMT₁ and hMT₂ melatonin receptors expressed in human embryonic kidney (HEK) 293 cells using both immunoblots and bioluminescent resonance energy transfer (BRET). Melatonin, neutral antagonists, and inverse agonists all promoted increases in BRET values for the MT₂ but not the MT₁. More recently, Ayoub et al. [113] demonstrated, using cell lines expressing low levels of MT₁ and/or MT₂ melatonin receptors and BRET to assess the pharmacological ligand binding profile, that the probability of MT₁/MT₂ heterodimer formation is similar to or even higher than those of the corresponding homodimers. Interestingly, both the MT₁ and MT₂ binding sites are functional within the heterodimer and the corresponding binding sites maintain their respective selectivity for MT₁ and MT₂ selective ligands. Together, these results suggest that oligomerization and heterodimerization of melatonin receptors may modulate trafficking and signaling responses by melatonin, which is an important factor to be taken into account when the pharmacology of new ligands is assessed.

2.4.3 Signaling

Mammalian MT₁ melatonin receptors signal through activation of pertussis toxin–sensitive and pertussis toxin–insensitive cellular pathways [47, 114]. Activation of G_i-coupled (G α_{i2} and G α_{i3}) MT₁ melatonin receptors inhibits forskolin-stimulated cAMP formation, protein kinase A (PKA) activity, and phosphorylation of the cAMP-responsive element binding protein (CREB) [115–117] (Fig. 2.3a). In recombinant systems, activation of the MT₁ melatonin receptor, via the release of the $\beta\gamma$ subunit, activates a Kir3 potassium channel and potentiates PGF_{2 α} stimulation of phospholipase C (PLC) activation and arachidonic acid release through a PTX (Pertussis toxin)-sensitive G protein [116, 118, 119]. MT₁ melatonin receptors also couple to stimulation of PLC-dependent signaling cascades either directly through G_q-mediated increases in phosphatidylinositol turnover and/or indirectly via G $\beta\gamma$ -mediated increases in intracellular calcium [116, 120] (Fig. 2.3a). In MCF-7 (Human Breast Adenocarcinoma-7) breast carcinoma cells and heterologous systems expressing MT₁ receptors activation of MT₁ melatonin receptors stimulates c-Jun N-terminal kinase activity via both pertussis toxin–sensitive (G α_i) and pertussis toxin–insensitive G (G α_s , G α_z , and G₁₆) proteins [121] and increases phosphorylation of MEK (mitogenic activated protein kinase-MAPK/extracellular regulated kinase-ERK kinase) 1 and 2 and extracellular regulated kinase (ERK) 1 and 2 [121, 122].

The MT₂ melatonin receptor expressed in heterologous cells inhibits forskolin-stimulated cAMP accumulation and decreased cGMP formation via the soluble guanylyl cyclase pathway and increases phosphoinositide turnover [51, 123, 124] (Fig. 2.3b). Activation of MT₂ melatonin receptors stimulates PKC activity in the rat SCN [125] and inhibits GABA_A receptor-mediated currents in the hippocampus [126].

Figure 2.3 Signaling events mediated by activation of MT₁ and MT₂ melatonin receptors. (a) Melatonin (MLT) signals through activation of MT₁ melatonin receptor via two parallel pathways mediated by α-subunit (i.e., inhibition of cAMP formation) and βγ subunits [i.e., potentiation of phosphoinositide turnover stimulated by a G_q-coupled receptor (R)] of G_i. (b) Signaling pathways coupled to MT₂ melatonin receptor activation. Melatonin-mediated phase shifts of circadian rhythms through MT₂ receptors are mediated by protein kinase C (PKC) activation (the mechanism leading to PKC activation remains putative, however). DAG, diacylglycerol; BK_{Ca}, calcium-activated potassium channel; cGMP, cyclic guanosine monophosphate; R, G_q-coupled receptor (i.e., prostaglandin PGF_{2α} receptor FP and purinergic receptor P2Y). (Reprinted from [71] with permission from Elsevier.)

In the rabbit retina the presynaptic melatonin heteroreceptor inhibiting dopamine release possesses the pharmacological characteristics of the MT₂ receptor [13, 52].

Melatonin receptor-mediated vasoconstriction and vasodilation through activation of MT₁ and MT₂ melatonin receptors, respectively, have been reported in peripheral and in cerebellar arteries of various species, including human [100,

127]. In smooth muscle, activation of MT₁ melatonin receptors potentiates α -adrenergic-mediated vasoconstriction by blocking BK_{Ca} via activation of G_i/G_o-protein-coupled MT₁ melatonin receptors and decreases in cAMP-mediated phosphorylation [128] (Fig. 2.3a). Participation of receptors localized in the endothelium in this response cannot be ruled out [100, 128, 129]. Melatonin-mediated vasoconstriction of cerebral arteries is blocked by the competitive melatonin receptor antagonists luzindole and S20928, by pertussis toxin, and by blockers of BK_{Ca} channels [130–132]. MT₁ melatonin receptor activation may regulate cerebral blood flow [127] as this receptor has been localized by immunohistochemistry in the arterial wall and hippocampal microvasculature of normal and Alzheimer's disease subjects. Vasoconstriction induced by melatonin may modulate vascular tone and attenuate diurnal fluctuations in blood pressure, keeping cerebral flow constant [133]. Increases in MT₁ receptor immunoreactivity in cerebral vessels from Alzheimer's subjects may result from decreases in melatonin levels associated with age and cerebral hypofunction associated with neurodegeneration [127].

Melatonin receptor-mediated vasodilation was demonstrated in rat arteries. Potentiation of phenylephrine-induced contractions by melatonin in caudal arteries is enhanced in the presence of the MT₂ selective receptor antagonists 4P-PDOT, suggesting blockade of a receptor involved in decreasing vascular tone, possibly the MT₂ receptor [100, 134]. Vasodilation and increase in blood flow induced by melatonin in distal skin regions may underlie the concomitant heat loss and hypothermic effect of this hormone [135]. Estrogens modulate melatonin receptor-mediated changes in vascular contractility. The vascular reactivity to melatonin varies during the estrous cycle, being reduced during proestrous, when the levels of estrogens are high as compared with other stages of the estrous cycle and following ovariectomy [136]. MT₁ and MT₂ melatonin receptors are also differentially regulated at the various stages of the estrous cycle and following treatment with 17 β -estradiol [103, 104]. 17 β -Estradiol increases the vasodilatory effect of melatonin through changes in MT₁- and/or MT₂-mediated sensitivity [104, 136]. Furthermore, estrogen appears to regulate the state of activation as recombinant MT₁ receptors expressed in heterologous cells and treated with 17 β -estradiol, and native ovarian MT₁ receptors during proestrous [104] are found to be constitutively active [103, 104]. Together, these reports suggest that either endogenous or exogenous estrogens may differentially regulate melatonin receptor function in mammals.

2.5 THE SUPRACHIASMATIC NUCLEUS

2.5.1 Circadian Inputs and Outputs

The mammalian circadian timing system formed by the retina, the intergeniculate leaflet (IGL), and the SCN facilitates adaptation of the organism to environmental changes through the rhythmic regulation of behavior and physiological processes. The SCN, a pair of small clusters of cells located within the anterior ventral hypothalamic area just above the optic chiasm, times the near 24-h oscillations of behavior, physiology, metabolic, and neuroendocrine function [137–139]. The SCN receives projections from the retina, directly through the retinohypothalamic tract and indirectly through the IGL and from numerous other brain regions, integrating

incoming signals and generating overt circadian rhythms [140, 141]. The SCN controls the circadian rhythm of melatonin synthesis by the pineal gland in both the presence and absence of light cues. In turn, pineal melatonin modulates clock function in the SCN through a direct action on two GPCRs, MT₁ and MT₂ [19].

Synchronization of endogenous circadian clocks to the 24-h period of the sleep–waking cycle occurs by the combined actions of neuronal transmission [142]: internal (e.g., GABA) and external (e.g., light) stimuli [138], secretion of SCN-regulated hormones (e.g., melatonin, corticosteroid) [143], and paracrine signals by secretion of tumor growth factor- α (TGF α) [144] and/or prokineticin (PK2) [145] that regulate motor activity and vasopressin (AVP) and vasoactive intestinal peptide (VIP) that regulate SCN output targets [142, 146].

2.5.2 Melatonin Receptors in SCN: Localization, Signaling, and Function

Biochemical, molecular, and functional evidence consistently suggests the presence of two melatonin receptors, MT₁ and MT₂, in the mammalian SCN. Expression of both the MT₁ and MT₂ melatonin receptor mRNAs in the rat and mouse SCN was demonstrated by reverse transcriptase polymer chain reaction (RT-PCR) and/or by in situ hybridization histochemistry using highly selective and specific digoxigenin-labeled oligonucleotide probes [50, 55, 61, 105, 125, 147–149]. Hybridization of mRNA with both the MT₁ and MT₂ antisense probes was observed within the cytoplasmic region of cells with neuronal morphology in rat SCN slices and SCN2.2 cells [125, 149] (Fig. 2.4). Expression of melatonin receptor proteins in the rodent and human SCN has been demonstrated by receptor autoradiography with 2-[¹²⁵I]iodomelatonin, Western blot analysis, and/or immunohistochemistry [150]; see also [52, 125, 149, 151, 152]. Western blot analysis with receptor-specific antiserum revealed expression of immunoreactive proteins of molecular size 37 kDa for both MT₁ and MT₂ melatonin receptors in rat SCN2.2 and SCN membranes [149]. These molecular weights correspond to those previously reported for the receptors in human kidney [153], rat hypothalamus and retina [154], and immortalized hypothalamic GT1–7 (gonatropin-releasing hormone neurons) cells [155]. In rat SCN membranes proteins of 55 kDa (MT₁) and 48 kDa (MT₂) may represent glycosylated forms of the receptors [149, 155]. Together these data demonstrated the expression of both MT₁ and MT₂ melatonin receptors in the mammalian SCN.

The MT₁ and MT₂ melatonin receptors expressed in the mammalian SCN are involved in acute inhibition of neuronal firing and phase shift of circadian rhythms. The mammalian SCN *in vitro* expresses a spontaneous circadian rhythm of neuronal firing rate with a peak of activity at CT 6 (circadian time 6; CT 12 onset of activity of host animal) or middle of the subjective day that persists *in vitro* for several cycles [139, 156, 157] (Fig. 2.5). Acute treatment with melatonin inhibits neuronal firing in the SCN, shifting the activity of the nucleus toward night levels [61, 158]. Rat SCN neurons show the highest sensitivity to melatonin's acute inhibition of neuronal firing between CT 12 and CT 15 [159], suggesting that endogenously produced melatonin may alter the state of excitability of neurons as the clock moves into the night. Melatonin inhibits neuronal firing in the rodent SCN through activation of MT₁ melatonin receptors as this effect was absent in the SCN of MT₁ knockout mice [61] and was not affected in the MT₂ knockout mice [62]. In the mouse SCN, melatonin inhibits pituitary adenylate cyclase-activating polypeptide (PACAP)-mediated

Figure 2.4 Melatonin receptor autoradiography and MT₁ and MT₂ mRNA expression in rat SCN. (a) Representative autoradiogram of 2-[¹²⁵I]iodomelatonin (2-[¹²⁵I]-IMLT) binding to rat SCN. To evaluate total binding (a), frozen coronal sections encompassing the SCN were incubated with 2-[¹²⁵I]iodomelatonin (200 pM). Nonspecific binding was determined by coincubation with melatonin (1 μM) and revealed no binding (data not shown). (b) Nissl stain of coronal section comprising SCN at similar magnification as (a). (c,d) Micrographs of hybridization signal for digoxigenin (DIG)-labeled MT₁ and MT₂ antisense oligonucleotide probes to rat SCN frozen sections. The hybridization signal was discretely localized throughout the SCN with both MT₁ antisense probe (c) and MT₂ antisense probe (d). No hybridization was detected with MT₁ and MT₂ sense probes (not shown). Scale bar, 0.5 mm. Insets: SCN cells taken from regions delineated by white squares in (c) and (d) at high magnification, demonstrating that hybridization to mRNA was restricted to the cytoplasm. Scale bar, 20 μm. [Modified (Figs. 1 and 2) from [125] with permission from the *American Journal of Physiology*.]

CREB phosphorylation [62, 160] through activation of MT₁ melatonin receptors, as these effects are not observed in the SCN from MT₁ knockout mice.

The master biological clock in the mammalian SCN is reset in response to melatonin at temporally distinct sensitive times, dusk (CT 9–11) and dawn (CT 22.2) (Fig. 2.5a) [138]. Melatonin and the MT₁/MT₂ nonselective melatonin analogs GR196429 (*N*-[2-[2,3,7,8-tetrahydro-1*H*-furo (2,3-*g*)indol-1-yl]ethyl]acetamide) [161] and S20098 (agomelatine) [162] induce a concentration-dependent phase advance of the circadian rhythm of neuronal firing when applied at CT 10 to the

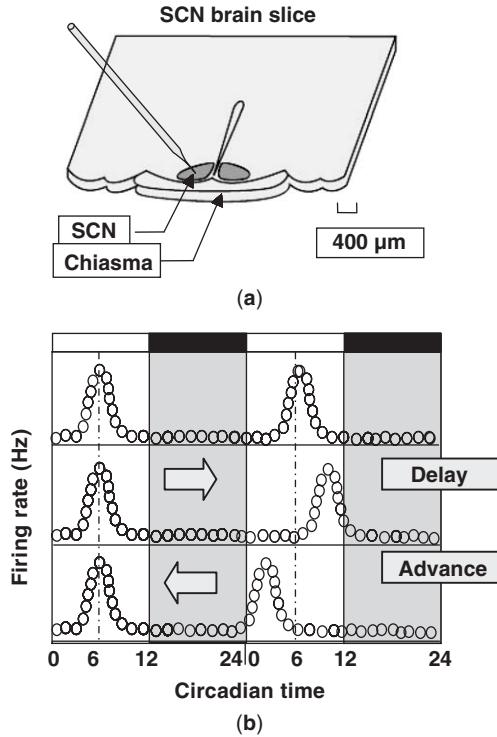

Figure 2.5 Circadian rhythms of neuronal firing in SCN brain slice. Schematic representation of a coronal slice (400 μm) of rodent brain containing SCN. The spontaneous rhythms of neuronal firing recorded from rodent SCN brain slices by extracellular recording follow a circadian pattern with a peak observed at mid-subjective day (CT 6–7) indicated by the dashed line. This peak can be used as a marker to assess the effect of various stimuli on clock phase. A *phase advance* of the peak is observed when the peak of neuronal activity appears earlier than in controls. A *phase delay* results from a stimulus that causes the peak of neuronal activity to occur later than in controls. The periods of sensitivity to induce phase advances or phase delays are unique for each stimuli and are constant on all mammalian species. (See color insert.)

rat and/or mouse SCN brain slice [125, 156, 163–165] (Fig. 2.5b). These melatonin-mediated phase advances are blocked by pertussis toxin and specific inhibitors of PKC [61, 156]. In the rat SCN brain slice activation of PKC by phorbol esters phase advance the circadian rhythm of neuronal firing when applied at either CT 10 or CT 23 [156]. Melatonin-mediated stimulation of PKC phosphotransferase activity at CT 10 is blocked by luzindole and MT_2 receptor selective concentrations of the antagonist 4P-PDOT [125]. Together, these data demonstrated that melatonin-mediated phase shifts of the circadian rhythm of neuronal firing are induced through activation of a G-protein-coupled PKC-mediated signaling pathway. The melatonin-mediated phase advances in rodent SCN brain slices are blocked by the MT_1/MT_2 competitive melatonin receptor antagonist luzindole [125, 164]. Melatonin application at CT 10 phase advances the circadian rhythm of neuronal firing in a concentration-dependent manner with identical potency in the SCN brain slice from both the wild-type and MT_1 knockout mice [61, 165]. These phase advances are completely blocked by MT_2 selective concentrations of the competitive

receptor antagonist 4P-PDOT [166]. Melatonin did not phase shift the circadian rhythm of neuronal firing in SCN brain slices from mice with genetic deletion of MT₂ receptors [167]. Taken together these results strongly suggest that activation of MT₂ melatonin receptors in the rodent SCN phase shift circadian rhythms of neuronal firing through an MT₂ receptor-mediated, PKC-dependent signaling pathway.

Immortalized cells from the rat SCN (SCN 2.2) retain most biochemical and biophysical characteristics of the native tissue, including the expression of clock genes, regulatory proteins, and rhythmic biological clock function [168, 169]. The SCN 1.4 and SCN 2.2 cell lines consist of a heterogeneous population of neuronal- and glial-like cells that show circadian patterns of 2-deoxyglucose uptake and neurotrophic factor 3 (NT-3) content, restored circadian wheel-running activity when transplanted into SCN-lesioned arrhythmic rats, and induced metabolic and molecular rhythmicity to cocultured NIH-3T3 fibroblasts and gated sensitivity to the glutamate- and melatonin-mediated phase shift of circadian rhythms [168–173]. Moreover, SCN 2.2 cells exhibit basal endogenous oscillations in PKC activity and modulation of PKC activity by melatonin at the same periods of sensitivity (CT 2 and CT 10) observed in the native SCN [125, 171]. SCN 2.2 cells expressed functional MT₁ and MT₂ receptors that localized onto cells with neuronal-like morphology [149]. Melatonin inhibits forskolin-stimulated cAMP formation through activation of G-protein-coupled melatonin receptors and stimulated PKC activity through activation of the MT₂ receptor [149]. Physiological concentrations of melatonin (300 pM) mimicking the nocturnal secretion (8 h) decreased MT₂ but not MT₁ melatonin receptor density in SCN 2.2 cells transiently expressing these receptors and desensitized endogenous MT₂ melatonin receptors coupled to PKC stimulation [173]. Together these results suggest that the melatonin-mediated inhibition of neuronal firing and of PACAP-induced CREB phosphorylation is mediated through activation of the MT₁ receptor while phase shifts of neuronal rhythms of firing rate in the SCN are mediated through activation of the MT₂ receptor. It is possible that the MT₁-mediated signaling pathway is involved in the regulation of circadian rhythms in output targets.

2.5.3 Melatonin Receptors and Clock Genes

Daily rhythms in behavior and physiology are driven by biological oscillators that synchronize endogenous rhythms with natural environmental cycles [137, 139]. The circadian signal is generated by autoregulatory transcriptional and translational feedback loops in the master biological clock as well as in other peripheral clocks in neuronal and nonneuronal cells. The CLOCK–BMAL1 transcription factors form heterodimers that drive the transcription of the mammalian period genes (*Per1*, *Per2*, *Per3*) and two cryptochrome genes (*Cry1*, *Cry2*) during the subjective day. In turn the Per and Cry proteins act as negative regulators of the feedback loop. The role of mPers is primarily to form complexes with mCRY and transport mCRY proteins into the nucleus [137, 174, 175]. Recently, a second, stabilizing feedback loop was characterized in mammals, where the nuclear receptors Rev-erb and ROR α and are respectively repressors and activators on the same RORE elements of the *Bmal1* promoter, generating the rhythms of *Bmal1* transcription [176, 177] (Fig. 2.1). The *timeless* (*Tim*) gene has an essential role in circadian clock function in *Drosophila*, while the putative mouse homolog *mTimeless* (*mTim*) is essential for embryonic

development [178]. The circadian function of mTIM in the mammalian clock has been controversial, as several publications reported no oscillation of *mTim* mRNA in the mammalian SCN [179, 180]. However, recently Tischkau et al. [181] reported a significant diurnal oscillation of *mTim* mRNA in the SCN. *mTim* appears to be essential for rhythmicity in the mouse SCN and it is part of the negative-feedback arm of the mammalian clockwork [182]. The short form of TIM (mTIM-s) is constitutively expressed in the SCN, while the full length (mTIM-fl) exhibits a diurnal oscillation [182]. Based on the time course of light-induced *mTim* and *mPer2* mRNA expression, it was suggested that mTIM interacts with mPER-s, with mPER2 being the preferred partner of mammalian TIM [182].

Photic and nonphotic stimuli modulates clock gene expression (e.g., *mPer1*, *mPer2*, and *mTim*) [76, 180, 181, 183–185]. Melatonin effects on clock gene expression and the molecular mechanism(s) by which the hormone changes clock phase have remained elusive. Most studies reported no change or very small changes on clock gene expression by melatonin in the rat SCN [186, 187]. Poirel and colleagues [187] observed changes in clock gene expression following melatonin administration to rats only on the second day after treatment. The fact that melatonin administration was outside the period of sensitivity for phase shift and conducted under a light–dark cycle together with a lengthy sampling interval may have contributed to the negative results. More recently, however, Isobe and Nishino (2004) [188] demonstrated increases in *mPer2* gene expression in the rat SCN 3 h after melatonin administration. Evidence suggests that *mTim* may be the clock gene regulated by melatonin. Disruption of SCN neuronal activity rhythms by application of antisense for the *mTim* clock gene phase shifts the clock generating a phase response curve of neuronal firing [182] that is opposite to the mammalian melatonin phase response curve [189], with maximum advances at CT 2–4 and phase at CT 10–12. Kandalepas et al. (2004) [190] reported that melatonin applied at CT 10 but not at CT 6 stimulated *mTim-fl* mRNA expression, an effect blocked by a PKC inhibitor. Together these results suggest a possible role for *mTim* in melatonin-mediated phase shift of circadian rhythms.

2.5.4 Regulation

Melatonin receptors, as other members of the GPCR superfamily, maintain timely cellular function and homeostasis by regulating signal transduction events through the process of desensitization and/or supersensitization. Desensitization is the waning of receptor responsiveness following persistent agonist challenge and can be characterized by uncoupling of receptor and G protein, receptor internalization, and/or receptor downregulation [109]. Supersensitization, by contrast, relates to enhanced responses generally resulting from persistent inhibition or blockade of a receptor [191].

In the rodent SCN, the density of endogenous melatonin receptors and mRNA expression follow either diurnal or circadian rhythms, with shapes varying among laboratories and experimental conditions, including sex, age, species, tissue, environmental conditions, and/or clock regulation [148, 192–194]. Specific 2-[¹²⁵I]iodomelatonin binding to the rodent SCN is attributed to MT₁ melatonin receptors, as the radioligand does not detect MT₂ binding sites and melatonin was shown to both positively and negatively regulate its own receptors. While radioligand binding to the rat SCN demonstrated an inverse relationship between receptor

density and serum melatonin levels [192, 195], other studies show higher receptor density at times when endogenous melatonin is high [47, 193]. Melatonin receptors expressed in the SCN appear to be regulated by endogenous melatonin, the master biological clock, and photic input from the retina [192–194, 196–198]. Interestingly, prolonged exposure to a concentration of melatonin mimicking nocturnal levels (400 pM) did not affect the number of recombinant MT₁ melatonin receptors expressed in mammalian cells, the affinity for melatonin, or the functional sensitivity of the receptor [90]. Together, these data suggest that the changes in MT₁ melatonin receptor sensitivity in the mammalian SCN may result from a combined effect of receptor activation by endogenous melatonin, crosstalk with receptors activated by photic input, and the circadian clock.

2.5.4.1 Desensitization. The MT₁ and MT₂ melatonin receptors are differentially regulated depending on the melatonin concentration used (physiological vs. supra-physiological), time of exposure, and cellular background. Prolonged exposure (8 h) of recombinant MT₁ receptors to supraphysiological concentrations of melatonin (100 nM) significantly increased the number of MT₁ melatonin receptors, decreased the affinity (K_i), and desensitized the MT₁ melatonin receptor-mediated stimulation of [³⁵S]GTPγS binding, without internalization of the receptor [199]. In contrast, prolonged exposure to a concentration of melatonin mimicking nocturnal levels (400 pM) did not affect the number of MT₁ melatonin receptors, the affinity for melatonin, or the functional sensitivity of the receptor [199]. Endogenous melatonin should not significantly affect the functional sensitivity of MT₁ melatonin receptors [199]; however, exogenous melatonin taken therapeutically at doses above physiological levels could desensitize the receptor, thereby affecting physiological responses mediated following activation of MT₁ melatonin receptors [200].

The MT₂ melatonin receptor exhibits rapid desensitization and internalization upon exposure to both physiological and supraphysiological concentrations of melatonin [90, 91]. Pretreatment with physiological concentrations of melatonin (30–300 pM or 7–70 pg/mL) decreased the number of hMT₂ melatonin receptors heterologously expressed in mammalian cells in a time- and concentration-dependent manner [91]. Furthermore, hMT₂-GFP (human MT₂-Green Fluorescent Protein) melatonin receptors heterologously expressed in immortalized SCN 2.2 internalized upon pretreatment with both physiological (300 pM or 70 pg/mL) and supraphysiological (10 nM or 2.3 ng/mL) concentrations of melatonin. The decrease in MT₂ melatonin receptor number induced by melatonin (300 pM for 1 h) was reversible and reached almost full recovery after 8 h; however, after treatment with 10 nM melatonin full recovery was not attained even after 24 h. This recovery process was partially protein synthesis dependent [91].

The functional sensitivity of endogenous MT₂ melatonin receptors in the rat SCN was studied by determining the ability of melatonin applied at CT 23 to phase advance the circadian rhythm of neuronal firing following pretreatment with physiological concentrations of melatonin (30–300 pM or 7–70 pg/mL) for a length of time mimicking the nocturnal surge (8 h). This treatment desensitized the MT₂ receptors precluding phase advances of the peak of neuronal firing, as the peak position was not different from that observed in SCN slices treated with vehicle for 8 h (Fig. 2.6) [91]. This functional desensitization is mediated through activation of MT₂ receptors by melatonin as it was completely blocked by cotreatment with

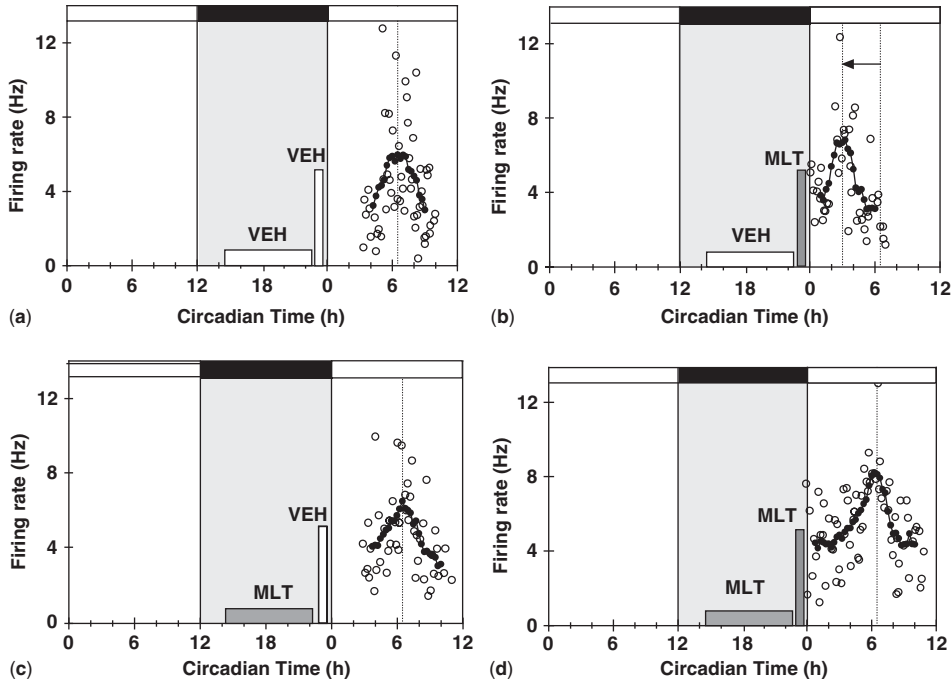

Figure 2.6 Desensitization of endogenous MT₂ melatonin receptors in rat SCN impaired melatonin-mediated phase shifts. Shown are representative rhythms of neuronal firing assessed by extracellular recording in rat coronal brain slices containing the SCN. The horizontal bar indicates pretreatment during subjective night with vehicle (CT 14.5–22.5) and melatonin (300 pM, 8 h) (CT 14.5–22.5). The vertical bar represents stimulation with either vehicle or melatonin (1 nM) applied by a 1-μL microdrop for 10 min at CT 23. Firing rates from individual cells in the SCN (open circles) are shown as well as the mean firing rates presented as running averages (filled circles). Phase shifts were visually determined with reference to the peak of the circadian rhythm of neuronal firing at CT 6.8 ± 0.1 ($n = 3$) (a) obtained after pretreatment with vehicle for 8 h and a vehicle pulse at CT 23. VEH: vehicle; MLT: melatonin. [Modified (Fig. 8) from [173] with permission from the *FASEB*.]

the MT₂ melatonin receptor antagonist 4P-PDOT [91]. Similarly, in rat immortalized SCN 2.2 cells, basal PKC activity shows a diurnal rhythm with nadirs during subjective day at CT 10 and CT 2 [171]. At these periods of sensitivity, melatonin stimulates PKC activity through activation of MT₂ melatonin receptors. Physiological concentrations of melatonin mimicking the nocturnal duration in vivo, desensitized the MT₂ melatonin receptor-mediated activation of PKC at CT 2. This effect was blocked by the competitive MT₂ melatonin receptor antagonist 4P-PDOT [91]. In vivo the nightly secretion of melatonin desensitizes endogenous MT₂ melatonin receptors in the mammalian SCN, thereby providing a temporally integrated profile of sensitivity of the mammalian biological clock to a melatonin signal.

2.5.4.2 Supersensitization. Activation of hMT₁ melatonin receptors by physiological concentrations of melatonin for a length of time mimicking the nocturnal surge increased hMT₁ melatonin receptor binding and induced functional supersensitiza-

tion of the cAMP signaling system upon withdrawal of the hormone [117, 201, 202]. This includes increase in cAMP formation, activation of protein kinase A, and phosphorylation of the transcription factor CREB [117, 203]. Indeed the circadian release of melatonin during the hours of darkness, through activation of high-affinity MT₁ melatonin receptors in target tissues, may inhibit stimulated cAMP formation resulting in supersensitization of cAMP signaling pathways linked to receptors coupled to G_s during the period of withdrawal [117, 201, 204]. It is therefore conceivable that melatonin-mediated supersensitization of the cAMP signaling pathway is a general mechanism by which the hormone transmits circadian signals through activation of CRE containing genes regulated by the transcription factor CREB [e.g., brain-derived neurotrophic factor (BDNF), *Per1* and *Per2* genes].

Clock genes are also found in many peripheral tissues, where the rhythms are delayed with respect to those observed in the SCN [137]. Peripheral rhythms of clock gene expression depend on neuronal and/or neuroendocrine output from the SCN [204, 205]. In the pars tuberalis (PT) and striatum, rhythms of *Per1* gene expression are dependent on the circadian melatonin signal possibly mediated through activation of MT₁ receptors in the target tissues [204, 206]. The PT of the pituitary rhythmically expresses *mPer1* and *mCry1* clock genes. In this tissue, melatonin increases *mCry1* expression during early subjective night while decreasing *Per1* expression during early subjective day [207]. In the PT, melatonin appears to be involved in setting the gain for incoming stimuli into target tissues as it facilitates the effect of adenosine on *mPer1* expression through supersensitization of adenylyl cyclase effect that is absent in the SCN [186]. A similar mechanism of adenylyl cyclase supersensitization leading to increasing cAMP production and insulin secretion has been described in pancreatic β cells upon prolonged melatonin pretreatment [208]. The circadian signal generated within the SCN and transmitted via the release of pineal melatonin may be the mechanism by which the master clock sends light and dark signals to other brain or peripheral tissues.

2.6 MELATONIN MODULATION OF CIRCADIAN RHYTHMS OF BEHAVIOR

Melatonin-mediated phase shifts of circadian rhythms occur at two windows of sensitivity that correspond to the hours around the day–night (dusk) and night–day (dawn) transitions [18, 55, 189, 209, 210]. Melatonin administered at the end of subjective day in vivo phase advances the onset of melatonin production in humans [18, 211–213] and of circadian activity rhythms in rodents [165, 189]. Figure 2.7 shows the melatonin-mediated phase advance of activity rhythm onset in both “melatonin-deficient” (C57BL/6) and “melatonin proficient” (C3H/HeN) mice [165, 214, 215]. Furthermore, in both mice and humans melatonin administered at the night–day transition phase delays circadian activity rhythms [189, 209]. As demonstrated with melatonin the nonselective MT₁/MT₂ melatonin receptor analogs S20098 and TAK 375 (Fig. 2.8) phase shift circadian rhythms of activity and accelerate reentrainment after a phase advance of the dark cycle in rodents [165, 216–219].

Pharmacological studies suggest that the melatonin-mediated phase shifts of circadian activity rhythm onset in the mouse in vivo [55] and of neuronal firing in the rat SCN brain slice in vitro [61, 91, 125, 156, 165] are mediated through activation

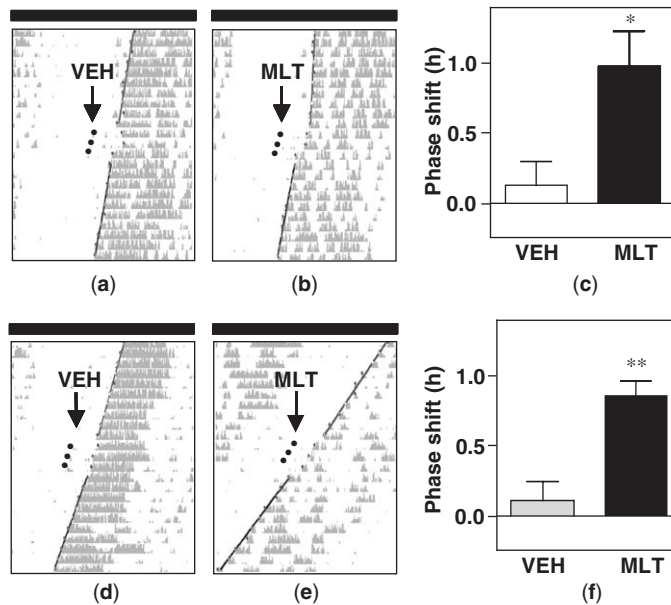

Figure 2.7 Melatonin phase advanced onset of wheel-running activity rhythms in C3H/HeN and C57BL/6 mice. Representative wheel-running activity actograms of individual C3H/HeN (a, b) or C57BL/6 (d, e) mice treated with vehicle (a, d) or melatonin (b, e). Wheel-running activity rhythms were recorded from mice kept in constant dark conditions. Mice were treated with either vehicle (3% ethanol/saline, s.c.) [(c) $n = 8$; (f) $n = 8$] or melatonin (90 $\mu\text{g}/\text{mouse}$, s.c.) [(c) $n = 10$; (f) $n = 8$] at CT 10 for three consecutive days. Black dots point to treatment time each day. (c, f) Bars represent mean \pm standard error of the mean (SEM) of phase shift of activity onset expressed in hours for vehicle- (VEH) and melatonin (MLT) treated C3H/HeN (c) and C57BL/6 (f) mice. (*) $P < 0.05$; (**) $P < 0.01$ when compared with vehicle treated. [Modified (Figs. 1 and 3) from [165] with permission from Blackwell Publishing.] (See color insert.)

of melatonin receptors. MT_2 selective concentrations of the competitive antagonist 4P-PDOT blocked melatonin-mediated phase shift of the circadian rhythm of neuronal firing in rat and mice SCN brain slices [125, 165, 166]. Furthermore, melatonin advances the peak of circadian rhythm of neuronal firing with identical potency in the SCN brain slices from either wild-type or MT_1 knockout mice, strongly suggesting the involvement of the MT_2 melatonin receptor [165]. Paradoxically, however, melatonin did not phase shift circadian rhythms of activity or accelerated reentrainment to a new dark onset after an abrupt advance of the dark cycle in C57B6/J mice [165]. Together, these data suggest that in vivo activation of molecular events regulated through MT_1 melatonin receptors within or outside the SCN and/or in output pathways may be necessary and perhaps sufficient for the expression of melatonin-mediated phase shifts of circadian rhythm of locomotor activity.

The pineal gland, through the release of the hormone melatonin, contributes to the integrity of circadian rhythmicity in mammals. This hypothesis is supported by reports demonstrating that daily melatonin administration enhances the organization of disrupted circadian rhythms [220], pinealectomy facilitates the loss of circadian rhythmicity in rodents kept in constant light [221], and melatonin administration in

Figure 2.8 Melatonin receptor ligands under investigation for treatment of insomnia, circadian sleep disorders, and depression: **S20098 (agomelatine, Valdoxan, Institut de Recherches Internationales Servier)**, *N*-[2-(7-methoxy-1-naphthyl)ethyl] acetamide; **TAK 375 (ramelteon, Rozerem, Takeda Pharmaceutical)**, (*S*)-*N*-[2-(1,6,7,8-tetrahydro-2*H*-indeno-[5,4-*b*]furan-8-yl)ethyl] propionamide; **LY 156735 (PD 6735, Eli Lilly and Co under development by Phase 2 Discovery)**, (*R*)-*N*-[2-(6-chloro-5-methoxy-1*H*-indol-3-yl) propyl]acetamide.

the diet corrects age-related changes in circadian response to environmental stimulus [222]. Additionally, nighttime melatonin appears to amplify and even restore disturbed circadian rhythms. In rats, daily melatonin administration amplifies the circadian rhythm of pineal norepinephrine content [223] and melatonin secretion [9] and restores the low-amplitude circadian rhythms of norepinephrine and acetylcholine synthesis in sympathetic ganglia, heart, and adrenal of aged rats [224] and the dampening of circadian rhythms of core body temperature induced by continuous illumination in rats [225]. The restored circadian rhythm of core body temperature persisted for several weeks after the last injection, suggesting that the synchronizing effect of melatonin resulted from its effect on SCN function. In humans, nighttime melatonin treatment amplifies the endogenous circadian melatonin secretion [226] and decreased blood pressure in male patients with essential hypertension [227]. Furthermore, melatonin supplementation increased nighttime rapid-eye-movement (REM) sleep and decreased core body temperature in patients with neuropsychiatric sleep disorders [228]. Together, these studies suggest that melatonin in addition to phase-shift circadian rhythms may play an important role in maintaining the integrity and amplitude of circadian rhythms of physiology.

2.7 MELATONIN RECEPTORS AS THERAPEUTIC TARGETS

Melatonin receptors are targets for the development of synthetic analogs to treat circadian and noncircadian sleep disorders. Currently three different nonselective MT₁/MT₂ melatonin receptor agonists (agomelatine, ramelteon, PD 6735) are under development for the treatment of insomnia, circadian rhythm disturbances, and depression (Fig. 2.8). The pharmacological properties as well as the potential therapeutic applications of these new investigational drugs are briefly described below.

2.7.1 Sleep

In humans the hormone melatonin produced in a circadian pattern with high levels at night promotes sleep at circadian phases when the SCN stimulates waking [17]. The observation that melatonin production is concurrent with nocturnal sleep and that the onset of evening melatonin production correlates with evening self-reported sleepiness and increased sleep propensity led to the hypothesis that melatonin and related ligands can be used to treat insomnia [17]. Insomnia is associated with daytime sleepiness and decrements in mental and physical performance. Involuntary insomnia occurs quite frequently due to endogenous or exogenous causes which do not allow sleep during the desired normal sleep time.

In normal volunteers physiological doses of oral melatonin (below 0.5 mg) which raise endogenous levels of the hormone to nocturnal levels are effective in decreasing sleep onset latency, oral temperature, and alertness [8, 35, 229]. Melatonin also promoted sleep in diurnal nonhuman primates and in human subjects suffering from age-related insomnia [200, 230, 231]. The sleep-promoting effects of melatonin are observed within an hour of administration, are independent of time of day, and are not mediated through interaction with benzodiazepine receptors [35, 232, 233]. Melatonin-mediated sleep promotion in humans is probably mediated through activation of melatonin receptors in the SCN and/or areas of the limbic system. Rodent studies suggest that melatonin-mediated decreases in neuronal activity are due to activation of MT₁ receptors [19, 61]. However, support for the hypothesis that this receptor is involved in melatonin-mediated sleep promotion in humans requires further investigation using pharmacological agents selective for the melatonin receptor types.

Ramelteon is a novel and nonselective high-affinity MT₁ and MT₂ melatonin receptor agonist with low affinity for the MT₃ binding sites that was developed for the treatment of insomnia and circadian sleep disorders [234] (Fig. 2.8). In cats [235] and monkeys [236] ramelteon promotes sleep, showing higher efficacy than melatonin. Ramelteon does not affect learning, memory, or motor function and is devoid of rewarding properties [237]. In humans with primary chronic insomnia, this novel melatonin receptor agonist decreases the latency to persistent sleep, increased total sleep time, and sleep efficiency [238]. The melatonin analog agomelatine, under development for the treatment of depressive disorders, also increases fatigue and reduces sleep latency in human volunteers [239]. In summary, melatonin as well as novel synthetic melatonin can induce physiological sleep without the common side effects frequently observed with sleep medication.

In subjects with moderate to severe sleep insomnia PD 6735 at 20, 50, and 100 mg in two consecutive days reduced sleep latency to persistent sleep as determined by polysomnography and reduced subjective sleep latency. PD 6735 did not negatively

affect other sleep parameters or produce morning-after psychomotor impairment [240]. PD 6735 does not show hypothermia, hypertension, and bradycardia, which are common side effects of melatonin [241].

2.7.2 Circadian Rhythms

Alterations between the timing of the endogenous sleep–wake cycle and the environmental light–dark cycle under conditions in which the sleep mechanisms are functionally intact lead to the so-called circadian sleep disorders. Circadian sleep disorders that involve alteration of the phase of the circadian clock with respect to the environment can be treated by timely administration of light or agents such as benzodiazepines or melatonin (for a review see [18]). These circadian sleep disorders include jet lag due to rapid crossing of time zones, shift work associated with changing work schedules, advanced sleep phase syndrome (ASPS) characterized by early sleep onset and offset of sleep, delayed sleep phase syndrome (DSPS) characterized by abnormal delay of sleep onset, and walking, non-24-h sleep–wake disorder characterized by irregular sleep–wake patterns [18]. Circadian sleep disorders also occur as a result of an abnormal light–dark cycle precluding the entrainment of endogenous rhythms to the 24-h period due to absence of environmental cues or a physical condition that altered the perception of light by the circadian system (e.g., blind individuals, tumor in the SCN). Treatment of circadian sleep disorders include chronotherapy [242], early-morning and early-evening light treatment [243, 244], and evening oral melatonin [245, 246].

In preclinical studies with normal volunteers agomelatine was found to phase shift circadian sleep patterns. Agomelatine administered in the early-evening phase advances core body temperature rhythms and increases the duration of REM sleep [239]. It also advances sleep termination, a phenomenon also observed upon administration of melatonin to subjects with DSPS [246]. Agomelatine advances the circadian phase of the salivary melatonin rhythm as well as the nocturnal regulation of core body temperature [239]. In these paradigms the effect of agomelatine was more pronounced with an oral dose of 100 mg, while melatonin was effective at a dose of 5 mg. PD 6735 was shown to accelerate readaptation of circadian rhythms following a stimulated 9-h phase advance in normal volunteers maintained in isolation [247]. Together, these studies demonstrate that these novel investigational new drugs have potential for the treatment of circadian rhythm disturbances.

2.7.3 Depression

Major depressive disorder is a common and serious psychiatric illness affecting between 10 and 15% of the adult population. The treatment of choice for this disorder is antidepressant medication. The introduction of selective serotonin reuptake inhibitors (SSRIs) has revolutionized treatment of depression providing efficacious therapy with lower toxicity and generally more tolerable side effects. Current investigational new treatments for depression use molecules with novel mechanism(s) of action, including pharmacological actions at melatonin receptors [99].

The melatonin system appears to be involved in the pathophysiology of affective disorders, namely depression. Melatonin and ligands with related pharmacological properties promote sleep and synchronize circadian rhythms, which are generally altered in major depression [248–250]. Dysregulation of the circadian release of

melatonin has been correlated with depressive states in clinical populations [251, 252]; however, it is unclear whether high or low melatonin levels, advanced or delayed phase, or amplitude irregularities contribute to depressive etiology or symptomology [253–258].

Melatonin and melatonin ligands exert antidepressant-like effects in several animal models of depression. Antidepressant treatment potentiates noradrenergic stimulation of pineal β adrenoceptors and hence melatonin production [258, 259]. Pharmacological doses of melatonin induce antidepressant-like effects in both mice and rats following a single or multiple swimming sessions [260–263] and in chronic mild stress paradigms in which sleep rhythms are disrupted [264]. The beneficial effects of melatonin in animal models of depression were strengthened by studies showing antidepressant-like effects of synthetic melatonin ligands. Overstreet et al. [265] reported that chronic but not acute administration of the melatonin receptor agonist S20304 (*N*-(2-(1-naphthyl)ethyl)cyclobutanecarboxamide) induced antidepressant-like effects in Flinders sensitive line (FSL) rats, which display innate high levels of immobility. Additionally, chronic administration of agomelatine, which activates both MT₁ and MT₂ melatonin receptors and blocks 5-HT_{2C} and 5-HT_{2B} receptors, induces antidepressant-like effects in rodents during forced swimming [263]. In contrast, melatonin shows no effect upon acute treatment or increased immobility in the swimming test [266, 267]. Interestingly, we demonstrated that the competitive melatonin receptor antagonist luzindole significantly decreased immobility in the swimming test [267]. The antidepressant-like effect of luzindole was observed in male and female C3H/HeN mice during the light and dark phases and was blocked in animals treated with melatonin [267, 268]. Luzindole decreases immobility during swimming in C3H/HeN wild-type mice and in mice with genetic deletion of MT₁ melatonin receptors but not in mice lacking the MT₂ receptor [268] (Fig. 2.9). These results suggest that luzindole may exert antidepressant-like effects through an action at MT₂ rather than MT₁ melatonin receptors.

Recently, attention focused on the antidepressant properties of agomelatine, a synthetic analog of the neurohormone melatonin that shows MT₁/MT₂ receptor agonist pharmacological properties and is a competitive 5-HT_{2C} and 5-HT_{2B} receptor antagonist [41, 269]. Studies in animals suggest that agomelatine may exert antidepressant and anxiolytic properties by a combination of action on MT₁ and MT₂ melatonin receptors and 5-HT_{2C} receptors [41, 270]; however, which is the relative contribution of each target to the overall effect is not known.

Agomelatine is a new antidepressant with a unique pharmacological profile that combines potential therapeutic actions on sleep, circadian rhythm dysfunction, and serotonin neurotransmission, which are known to be altered in depression. Agomelatine is significantly more effective than placebo in the treatment of major depression. At a dose of 25 mg agomelatine significantly reduced the depression scores as determined by the 17-item Hamilton Rating Scale for Depression (HAM-D) and several other criteria [269, 271]. Agomelatine significantly reduced the HAM-D scores after two weeks of treatment, showing higher efficacy than paroxetine, which was effective after four weeks treatment [271]. Both agomelatine and paroxetine were effective in the treatment of anxiety symptoms associated with depression [271]. Agomelatine is well tolerated with an adverse effect profile including discontinuation symptoms comparable to that of placebo and below that of paroxetine [271–273]. Paroxetine, an SSRI, has a half-life of 24 h while that of agomelatine is 2 h [272].

Figure 2.9 Effect of luzindole on swimming test immobility in C3H/HeN WT, MT₁ KO, and MT₂ KO young male mice during dark phase. The ordinate represents total immobility time during 4 min of a 6-min swimming session expressed in seconds. Male mice (2.5 months old) were treated with either vehicle (VEH) or luzindole (LUZ) (30 mg/kg, i.p.) 30 min prior to the forced swimming test. Luzindole treatment during the dark phase (ZT 20–22) significantly decreased time spent immobile in both wild-type (WT) and MT₁ knockout (KO) mice as compared with vehicle-treated [(a) WT and MT₁ KO; (b) WT] but not in the MT₂ KO mice as compared with the corresponding vehicle-treated controls. Bars represent mean \pm SEM of 6–8 (a) and 10 (b) mice per group. (*) $P < 0.001$ as compared with vehicle treated. [Modified (Figs. 1 and 5) from [268] with permission from Blackwell Publishing.]

Agomelatine appears to be superior over other current antidepressant treatments as it promotes sleep [239, 274], entrains circadian rhythms [211, 275], and shows anxiolytic effects and shorter onset of therapeutic effectiveness [269, 270, 272]. It induces dizziness; however, it lacks prominent side effects shown by most classes of antidepressants, such as sexual dysfunction, gastrointestinal reactions, and discontinuation symptoms [269, 272, 276]. Together, these results suggest that agomelatine, with a pharmacokinetic and pharmacological profile distinct from that of other antidepressant, appears to be more effective with faster onset of action and better adverse effect profile than currently prescribed antidepressant medications.

3.1 INTRODUCTION

Narcolepsy is characterized by excessive daytime sleepiness (EDS), cataplexy, and other dissociated manifestations of rapid-eye-movement (REM) sleep (hypnagogic hallucinations and sleep paralysis). Narcolepsy is currently treated with amphetamine-like central nervous system (CNS) stimulants (for EDS) and antidepressants (for cataplexy). Some other classes of compounds, such as modafinil (a nonamphetamine wake-promoting compound for EDS) and γ -hydroxybutyrate (GHB, a short-acting sedative for EDS/fragmented nighttime sleep and cataplexy), given at night are also employed. The major pathophysiology of human narcolepsy has recently been revealed by the extension of discoveries of narcolepsy genes in animal models: About 90% of human narcolepsy–cataplexy has been found to be hypocretin/orexin ligand deficient. This directly led to the development of new diagnostic tests [i.e., cerebrospinal fluid (CSF) hypocretin measures]. Hypocretin replacement is also likely to be a new therapeutic option for hypocretin-deficient narcolepsy, but this is still not available in humans. In this review, the pharmacological aspects of narcolepsy and related disorders are discussed.

3.2 SYMPTOMS OF NARCOLEPSY

Narcolepsy is a syndrome of unknown etiology (prevalence 1 in 2000 [1, 2]) characterized by EDS that is often profound. About 95% of narcoleptic cases are sporadic, but it also occurs in familial forms. Narcolepsy usually occurs in association with cataplexy and other symptoms and signs, which commonly include hypnagogic hallucinations or hypnopompic hallucinations, sleep paralysis, automatic behavior, and disrupted nocturnal sleep (Table 3.1) [3]. Symptoms most often begin during

TABLE 3.1 Clinical Characteristics of Narcolepsy–Cataplexy, Narcolepsy Without Cataplexy, and Idiopathic Hypersomnia

	Daytime sleepiness		Other Symptoms	MSLT		HLA-DQB1*0602	Low CSF Hypocretin Levels
	Duration	Awaken-Refreshed		Sleep Latency ^a	SOREMPS	Positivity	(<110 pg/mL)
Narcolepsy–cataplexy	Short (<30 min)	(+)	Cataplexy, REM sleep–related symptoms	<8 min	≥2	>90%	85–90% >90% in HLA positive
Narcolepsy without cataplexy	Short (<30 min)	(+)	Cataplexy (–), REM sleep–related symptoms	<8 min	≥2	40–50%	10–20% (almost all HLA positive)
Idiopathic hypersomnia with long sleep time	Long (>30 minutes)	(–)	Cataplexy (–), prolonged nighttime sleep (>10 h), autonomic nervous dysfunction	<8 min	≤1	No consistent results	Normal
Idiopathic hypersomnia without long sleep time	Varied	(–)	Cataplexy (–), no prolonged nighttime sleep (<10 h), autonomic nervous dysfunction	<8 min	≤1	No consistent results	Normal

Abbreviations: MSLT, multiple sleep latency test; HLA, human leukocyte antigen; SOREMP, sudden-onset rapid-eye-movement period.

^aLess than 8 minutes (instead of 5 minutes) was considered for the second revision of the International Classification of Sleep Disorders.

adolescence or young adulthood. However, narcolepsy may also occur earlier in childhood or not until the third or fourth decade of life. Quality-of-life studies suggest that the impact of narcolepsy is equal to that of Parkinson's disease [4]. Although EDS is not specific for narcolepsy and is seen in other primary and secondary EDS disorders (such as sleep apnea syndrome), cataplexy is generally regarded as pathognomonic. Occurrence of cataplexy is tightly associated with loss of hypocretin neurotransmission [5], and it rarely occurs as an isolated symptom. Cataplexy occasionally occurs in conjunction with other neurological conditions, such as Nieman–Pick type C disease, but the pathophysiological links in these neurological conditions with the hypocretin abnormalities are not yet well established [6].

3.2.1 Sleepiness or Excessive Daytime Sleepiness

As with the sleepiness of other sleep disorders, the EDS of narcolepsy presents itself with an increased propensity to fall asleep, nod, or easily doze in relaxed or sedentary situations or a need to exert extra effort to avoid sleeping in these situations [7]. Additionally, irresistible or overwhelming urges to sleep commonly occur from time to time during wakeful periods in the untreated patient with narcolepsy. These so-called sleep attacks are not instantaneous lapses into sleep, as is often thought by the general public, but represent the episodes of profound sleepiness experienced by those with marked sleep deprivation or other severe sleep disorders. In addition to frank sleepiness, the EDS of narcolepsy (as in other sleep disorders) can cause related symptoms, including poor memory, reduced concentration or attention, and irritability. Narcoleptic subjects feel refreshed after a short nap, but this does not last long and they become sleepy again within a few hours (Table 3.1). Narcolepsy may therefore consist of an inability to maintain wakefulness combined with the intrusion of REM sleep–associated phenomena (hypnagogic hallucinations, sleep paralysis, and possibly cataplexy; see below) into wakefulness.

3.2.2 Cataplexy

Cataplexy is the partial or complete loss of bilateral muscle tone in response to a strong emotion [7]. Reduced muscle tone may be minimal, occur in a few muscle groups, and cause minimal symptoms such as bilateral ptosis, head drooping, slurred speech, or dropping things from the hand or may be so severe that total body paralysis occurs, resulting in complete collapse. Cataplectic events usually last from a few seconds to 2 or 3 min but occasionally continue longer [8]. The patient is usually alert and oriented during the event despite the inability to respond. Positive emotions such as laughter more commonly trigger cataplexy than negative emotions; however, any strong emotion is a potential trigger [9]. Startling stimuli, stress, physical fatigue, or sleepiness may also be important triggers or factors that exacerbate cataplexy.

The current international criterion for narcolepsy does not require cataplexy for diagnosing narcolepsy if REM sleep abnormalities (i.e., SOREMPs during MSLT) are objectively documented (Table 3.1). According to epidemiological studies, cataplexy is found in 60–100% of patients with narcolepsy. A large range in the percentage affected with cataplexy is reported because the definitions of narcolepsy vary among studies (and by use of different diagnostic criteria). The onset of cataplexy is most frequently simultaneous with or within a few months of the onset of EDS, but in some cases, cataplexy may not develop until many years after the initial onset of EDS [8].

3.2.3 Hypnagogic or Hypnopompic Hallucinations

These phenomena may be visual, tactile, auditory, or multisensory events that are usually brief but occasionally continue for a few minutes that occur at the transition from wakefulness to sleep (hypnagogic) or from sleep to wakefulness (hypnopompic) [7]. Hallucinations may contain elements of dream sleep and consciousness combined and are often bizarre or disturbing to patients.

3.2.4 Sleep Paralysis

Sleep paralysis is the inability to move, lasting from a few seconds to a few minutes, during the transition from sleep to wakefulness or from wakefulness to sleep [7]. Episodes of sleep paralysis may alarm patients—particularly those who experience the sensation of being unable to breathe. Although accessory respiratory muscles may not be active during these episodes, diaphragmatic activity continues and air exchange remains adequate.

Other commonly reported symptoms include automatic behavior—“absent-minded” behavior or speech that is often nonsensical which the patient does not remember—and fragmented nocturnal sleep—frequent awakenings during the night.

Hypnagogic hallucinations, sleep paralysis, and automatic behavior are not specific to narcolepsy and occur in other sleep disorders (as well as in healthy individuals); however, these symptoms are far more common and occur with much greater frequency in narcolepsy [7].

3.3 NARCOLEPSY EVALUATION

3.3.1 Polysomnography: Nocturnal and Daytime Sleep Studies

Nocturnal polysomnography is not essential in the diagnostic workup when straightforward cataplexy accompanies EDS. However, it remains an important part of the evaluation process primarily to exclude other conditions that occur in narcolepsy at a higher than normal rate (obstructive sleep apnea, periodic limb movement syndrome, and REM sleep behavior disorder) and could add to the sleepiness or nocturnal sleep disruption the patient may be experiencing [10]. Additionally, SOREMPs during nocturnal polysomnography may be witnessed and are also supportive for the diagnosis.

Daytime nap studies (in the form of the MSLT), usually demonstrate substantially reduced sleep latency and SOREMPs in patients with narcolepsy. Average MSLT sleep latencies for narcolepsy with cataplexy are approximately 2–3 min [11]; however, substantial variability across and within patients can, at times, be seen, and mean sleep latencies of less than 5 min during the MSLT are used for the International Classification of Sleep Disorders (ICSD) (less than 8 min was considered in the second revision of the ICSD) (Table 3.1). SOREMPs are also not specific for narcolepsy, but the occurrence of two or more of these events during the MSLT in the setting of objectively marked sleepiness and without any other explanation for their occurrence (such as sleep deprivation, REM-suppressant medication rebound, altered sleep schedule, obstructive sleep apnea, or delayed sleep-phase syndrome) is suggestive of narcolepsy.

3.3.2 Cerebrospinal Fluid Hypocretin-1 Assessment

As discussed in the Section 3.5, many (about 90% of narcolepsy–cataplexy subjects), but not all, patients with narcolepsy have very low or undetectable levels of hypocretin-1/orexin A in the CSF [5, 12]. Such low levels of CSF hypocretin-1 are relatively specific for narcolepsy–cataplexy but are also seen in a few other neurological conditions, such as a subset of patients with Guillain–Barré syndrome and Ma2 positive paraneoplastic syndrome [13, 14]. Since these conditions are clinically distinct from narcolepsy, low CSF hypocretin levels in these conditions do not confound their diagnostic values. When used to assess patients for narcolepsy, low CSF hypocretin-1 appears to be a more specific test than the MSLT and CSF hypocretin-1 levels (Table 3.1). Therefore, low CSF hypocretin-1 levels (less than 110 pg/mL) was included for the second revision of ICSD. Previously, no specific and sensitive diagnostic test for narcolepsy based on the pathophysiology of the disease was available, and the final diagnosis was often delayed for several years after the disease onset, which is typically during adolescence [15]. Many patients with narcolepsy and related EDS disorders are therefore likely to obtain immediate benefit from this new specific diagnostic test.

3.3.3 Histocompatibility Human Leukocyte Antigen Testing

A very strong but incomplete correlation exists between narcolepsy (with cataplexy) and the human leucocyte antigen (HLA) subtype DQB1*0602, yet this subtype is very common in the general population (approximately 20% in the combined U.S. population) and is neither specific nor sensitive for narcolepsy [2]. HLA testing is therefore not useful in confirming or excluding the diagnosis of narcolepsy and, in fact, may lead a clinician to inappropriate diagnostic conclusions (see also Section 3.5).

3.4 IDIOPATHIC HYPERSOMNIA AND OTHER PRIMARY EDS

Less common forms of hypersomnia include the idiopathic and recurrent hypersomnias [16]. Idiopathic hypersomnia is marked by excessive nocturnal sleep of good quality and by EDS which is not as severe as in the narcoleptic patients (but no refreshing after naps) and which is not REM sleep related (Table 3.1). The best characterized recurrent hypersomnia is the Kleine–Levin syndrome (KLS), a pervasive functional disorder of the hypothalamus characterized by hypersexuality, binge eating, and irritability associated with periods of EDS and sleep periods as long as 18–20 h [17, 18]. For details of clinical symptoms and treatments of these primary EDS, refer to [16].

3.5 PATHOPHYSIOLOGY OF NARCOLEPSY

3.5.1 Pathophysiological Consideration of Symptoms of Narcolepsy

The similarity between cataplexy and REM sleep atonia [the presence of frequent episodes of hypnagogic hallucinations and of sleep paralysis and the propensity for narcoleptics to go directly from wakefulness into REM sleep (i.e., SOREMs)]

suggests that narcolepsy is primarily a “disease of REM sleep” [19]. This hypothesis may, however, be too simplistic and does not explain the presence of sleepiness during the day and the short latency to both non-REM (NREM) and REM sleep during nocturnal and nap recordings. Another complementary hypothesis is that narcolepsy results from the disruption of the control mechanisms of both sleep and wakefulness or, in other words, of the vigilance state boundary problems [20]. According to this hypothesis, a cataplectic attack represents an intrusion of REM sleep atonia during wakefulness, while the hypnagogic hallucinations appear as dreamlike imagery taking place in the waking state, especially at sleep onset in patients who frequently have SOREMs.

Cataplexy is associated with an inhibition of the monosynaptic H reflex (a muscle response with monosynaptic latency due to excitation of Ia afferents in the spinal cord) and the polysynaptic deep-tendon reflexes [21]. In control subjects, it is only during REM sleep that the H reflex is totally suppressed. This finding highlights the relationship between the inhibition of motor processes during REM sleep and the sudden atonia and areflexia seen during cataplexy. Studies in canine narcolepsy, however, suggest that the mechanisms for the induction of cataplexy are different from those for REM sleep [22]. Furthermore, an extended human study confirmed that cataplexy correlates much more highly to hypocretin-deficient narcolepsy (see below), in contrast to other REM sleep-related phenomena [5]. Cataplexy may thus be viewed as somewhat distinct from other REM-related symptoms and as a hypocretin-deficiency pathological phenomenon. The fact that patients with other sleep disorders, such as sleep apnea, and even healthy controls can manifest SOREMs, hypnagogic hallucinations, and sleep paralysis when their sleep-wake patterns are sufficiently disturbed yet these subjects never develop cataplexy provides further support to the proposal that cataplexy may be unrelated to other REM-associated symptoms [23–26]. Although cataplexy and REM sleep atonia have great similarity and possibly share a common executive system, it is not necessary for the regulatory mechanism of both states to be identical. The mechanism of emotional triggering of cataplexy remains undetermined.

3.5.2 HLA: Immune System and Narcolepsy

An abundant amount of research into the HLA association in narcolepsy has been conducted which has yielded important discoveries. However, the research has yet to provide clinically meaningful information. This work therefore is only very briefly addressed in this review. A remarkably high HLA association with narcolepsy was discovered in the early 1980s [27]. Since the time of this initial finding, a variety of research across multiple ethnic groups has corroborated the existence of this strong HLA association. The most specific marker of narcolepsy in a number of different ethnic groups studied to date is DQB1*0602 [2]. This association is seen in an average of approximately 90% of those with unequivocal cataplexy [28]. Importantly, this association is substantially lower (only approximately 40%) in individuals who have received the diagnosis of narcolepsy but do not have cataplexy (Table 3.1).

The strong association between HLA type and narcolepsy with cataplexy raises the possibility that narcolepsy is an autoimmune disease [29]. There is, however, no evidence of inflammatory processes or immune abnormalities associated with narcolepsy [29], and studies have found no classical auto-antibodies and no increase in oligoclonal CSF bands in narcoleptics [30]. Typical autoimmune pathologies

(erythrocyte sedimentation rates, serum immunoglobulin levels, C-reactive protein levels, complement levels, and lymphocyte subset ratios) are apparently normal in narcoleptic patients [31]. In contrast, a variety of serological tests performed in narcoleptics, along with age- and sex-matched controls, yielded higher levels of antistreptolysin 0 and anti-DNase antibodies in narcoleptics than in controls [32, 33]. In view of these preliminary data, further exploration of possible immune-related dysfunction in narcolepsy is warranted.

3.5.3 Deficiency in Hypocretin (Orexin) Transmission in Canine and Human Narcolepsy

Narcolepsy has been described in several animal species, including dogs and most recently genetically engineered mice and rat models. Canine narcolepsy is a naturally occurring model, with both sporadic (17 breeds) and familial forms (Doberman, Labrador, and Dachshund). In Doberman pinschers and Labrador retrievers, the disease is transmitted as a recessive autosomal trait with complete penetrance [34].

In 1999, using positional cloning and gene-targeting strategies, two groups independently revealed the pathogenesis of narcolepsy in animals. The lack of the hypothalamic neuropeptide hypocretin/orexin ligand [preprohypocretin/orexin gene knockout (KO) mice] [35] or mutations in one of the two hypocretin/orexin receptor genes [hypocretin receptor 2 (*Hcrtr2*) gene in autosomal recessive canine narcolepsy] [36] was observed to result in narcolepsy. After extensive screening (especially in familial and early-onset human narcolepsy), it was demonstrated that mutations in hypocretin-related genes are rare: Only a single case with early-onset (six months of age) was found to be associated with a single point mutation in the preprohypocretin gene [37]. This result was however not surprising considering the fact that a large majority of human narcolepsy cases are sporadic. Even in rare familial cases of narcolepsy, it is unlikely that high-penetrant single genes (like hypocretin related genes) are involved.

Despite the lack of genetic abnormalities in the hypocretin system, it was found that the large majority (85–90%) of patients with narcolepsy–cataplexy have low or undetectable hypocretin-1 ligand in their CSF [12, 38] (Fig. 3.1). This hypocretin deficiency is tightly associated with the occurrence of cataplexy and HLA-DQB1*0602 positivity [5, 39, 40]. Postmortem human studies (utilizing a few brains) have confirmed hypocretin ligand deficiency (both hypocretin 1 and 2) in the narcoleptic brain [37, 41] (Fig. 3.1). Hypocretin deficiency has also been observed in sporadic cases of canine narcolepsy (seven of seven currently studied; the result of four cases are reported), suggesting that the pathophysiology in these animals mirrors that of most human cases [42].

Although the etiology of hypocretin deficiency in humans still needs to be determined, the fact that a large majority of human narcolepsy–cataplexy subjects are hypocretin ligand deficient suggests that hypocretin agonists may be promising in the treatment of narcolepsy (see Section 3.8).

3.5.4 Hypocretin /Orexin System and Sleep Regulation

Hypocretins/orexins were only recently discovered (in 1998, one year prior to the cloning of the canine narcolepsy gene) by two independent research groups. One

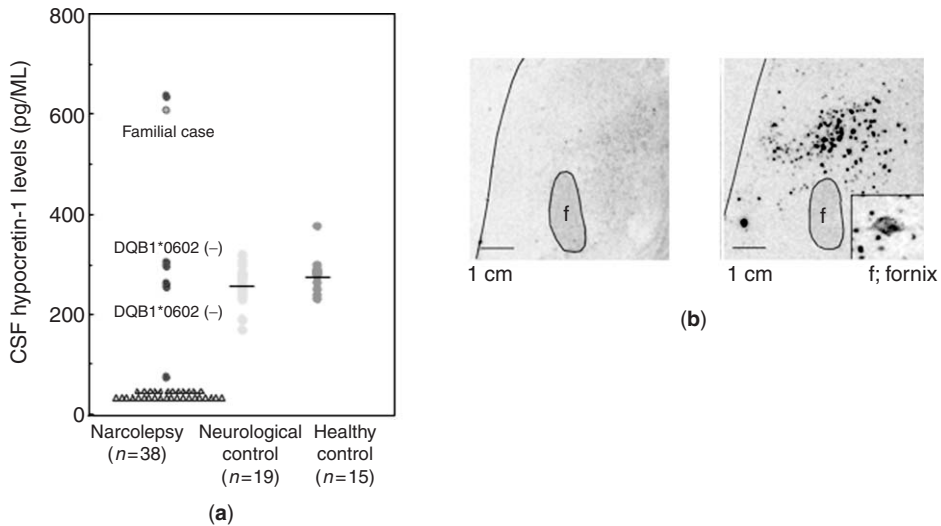

Figure 3.1 (a) CSF hypocretin-1 levels in narcoleptic and control subjects. CSF hypocretin-1 levels are undetectably low in most narcoleptic subjects (84.2%). Note that two HLA DQB1*0602 negative and one familial case have normal or high CSF hypocretin levels. (b) Preprohypocretin mRNA in situ hybridization in the hypothalamus of control and narcoleptic subjects. Preprohypocretin transcripts are detected in the hypothalamus of control (right) but not narcoleptic (left) subjects. Melanin-concentrating hormone (MCH) transcripts are detected in the same region in control and narcoleptic sections (data not shown). (See color insert.)

group called the peptides “hypocretin” because of their primary hypothalamic localization and similarities with the hormone secretin [43]. The other group called the molecules “orexin” after observing that central administration of these peptides increased appetite in rats [44]. Hypocretins 1 and 2 are produced exclusively by a well-defined group of neurons localized in the lateral hypothalamus. The neurons project to the olfactory bulb, cerebral cortex, thalamus, hypothalamus and brain stem, particularly the locus ceruleus (LC), raphe nucleus, and cholinergic nuclei (the laterodorsal tegmental and pedunculopontine tegmental nuclei), and cholinceptive sites (such as pontine reticular formation) thought to be important for sleep regulation [45] (Fig. 3.2).

A series of recent studies have now shown that the hypocretin system is a major excitatory system that affects the activity of monoaminergic [dopamine (DA), norepinephrine (NE), serotonin (5-HT), and histamine] and cholinergic systems with major effects on vigilance states [46, 47] (Fig. 3.2). It is thus likely that a deficiency in hypocretin neurotransmission induces an imbalance between these classical neurotransmitter systems, with primary effects on sleep state organization and vigilance (Fig. 3.2). Indeed, DA and/or NE contents have been reported to be high in several brain structures in narcoleptic Dobermans and in human narcolepsy brains postmortem [48]. These changes are possibly due to compensatory mechanisms, since the drugs that enhance dopaminergic neurotransmission [such as amphetamine-like stimulants and modafinil (for EDS)] and NE neurotransmission [such as noradrenaline uptake blockers (for cataplexy)] are needed to subside the symptoms of narcolepsy [48]. Histamine is another monoamine implicated in the

control of vigilance, and the histaminergic system is also likely to indirectly mediate the wake-promoting effects of hypocretin [49–51]. Interestingly, brain histamine contents both in *hcrtr2* gene mutated and ligand-deficient narcoleptic dogs are dramatically reduced [52]. It is thus interesting to further evaluate the involvement of the histaminergic system in the pathophysiology of narcolepsy and therapeutic applications of histaminergic compounds [53].

Many measurable activities (brain and body) and compounds manifest rhythmic fluctuations over the 24-h period. Whether hypocretin tone changes with *zeitgeber* time was assessed by measuring extracellular hypocretin-1 levels in the rat brain CSF

across 24-h periods using *in vivo* dialysis [54–56]. The results demonstrate the involvement of a slow diurnal pattern of hypocretin neurotransmission regulation (as in the homeostatic and/or circadian regulation of sleep). Hypocretin levels increase during the active periods and are highest at the end of the active period, and the levels decline with the onset of sleep. Furthermore, sleep deprivation increases hypocretin levels [54–56].

Changes in firing of hypocretin neuronal across different sleep stages were recently reported in rats; hypocretin neurons are wake-active and their activities reduce during slow wave sleep (SWS) and REM sleep [56a,b]. Regardless of the firing pattern of the hypocretin neurons, our results however suggest that basic hypocretin neurotransmission fluctuates across the 24-h period and slowly builds up during the active period. Adrenergic LC neurons are typical wake-active neurons involved in vigilance control, and it has been recently demonstrated that basic firing activity of wake-active LC neurons also significantly fluctuates across various circadian times [57].

Several acute manipulations such as exercise, low glucose utilization in the brain, and forced wakefulness increase hypocretin levels [46, 55, 58]. It is therefore hypothesized that a buildup/acute increase of hypocretin levels may counteract homeostatic sleep propensity that typically increases during the daytime and during forced wakefulness [55]. Due to the lack of increase in hypocretin tone, narcoleptic subjects may not be able to stay awake for a prolonged period and do not respond to various alerting stimuli. Conversely, reduction of the hypocretin tone at sleep onset may contribute to the profound deep sleep that normally inhibits REM sleep at sleep onset, and the lack of this system in narcolepsy may allow the occurrence of REM sleep at sleep onset.

Figure 3.2 (a) Monoaminergic and cholinergic control of sleepiness and cataplexy in relation to hypocretin input: schematic perspective. The stimulation of adrenergic transmission by adrenergic uptake inhibitors potently reduces cataplexy; this pharmacological property is likely involved in the mode of action of currently used anticataplectic agents (e.g., tricyclic antidepressants). The fact that both presynaptic α_2 autoreceptor stimulation and postsynaptic α_1 blockade aggravate cataplexy is consistent with an inhibitory role of adrenergic transmission in the control of REM sleep atonia. Dopaminergic uptake inhibitors have no effect on cataplexy, although these compounds strongly induce electrocortical arousal. In contrast, D_2/D_3 autoreceptor stimulation aggravates both cataplexy and sleepiness. Since DA uptake inhibitors are reported to be mostly active at the level of mesocortical and mesolimbic DA terminals, DA projections to these regions may be more involved in mediating EEG arousal. Muscarinic M_2 stimulation induces behavioral wakefulness and cortical desynchrony in control dogs, while it induces cataplexy in narcoleptic dogs. Although muscarinic antagonists reduce cataplexy in the canine model, attempts to use this class of compounds in humans have not been successful mainly due to the side effects. (b) Projections of hypocretin neurons in the rat brain and relative abundances of hypocretin receptor 1 and 2. It was recently revealed that hypocretin-containing neurons project to these previously identified monoaminergic and cholinergic and cholinceptive regions where hypocretin receptors are enriched. Impairments of hypocretin input may thus result in cholinergic and monoaminergic imbalance and generation of narcoleptic symptoms. VTA, ventral tegmental area; SN, substantia nigra; LC, locus ceruleus; LDT, laterodorsal tegmental nucleus; PPT, pedunculopontine tegmental nucleus; PRF, pontine reticular formation; BF, basal forebrain; VLPO, ventrolateral preoptic nucleus; LHA, lateral hypothalamic area; TMN; tuberomammillary nucleus; DR, dorsal raphe. (See color insert.)

3.6 TREATMENTS OF NARCOLEPSY

Nonpharmacological treatments (i.e., by behavioral modification) are often reported to be useful additions to the clinical management of narcoleptic patients [59–62]. Regular napping usually relieves sleepiness for 1–2 h [59] and is the treatment of choice for some patients, but this often has negative social and professional consequences. Exercising to avoid obesity, keeping a regular sleep–wake schedule, and having a supportive social environment (e.g., patient group organizations and support groups) are also helpful. In almost all cases, however, pharmacological treatment is needed, and 94% of patients reported using medications in a recent survey by a patient group organization [63].

3.6.1 Pharmacological Treatment of EDS with Amphetamine-Like Compounds

Amphetamine was first synthesized in 1897, but its stimulant effect was only recognized in 1929 by Alles. In 1935, amphetamine was used for the first time for the treatment of narcolepsy, and this was possibly the first condition for which amphetamine was used clinically, and it also revolutionized therapy for the condition (even though it was not a curative). The piperazine derivative of amphetamine, methylphenidate, was introduced for the treatment of narcolepsy in 1959 by Yoss and Daly [64], but both compounds share similar pharmacological properties.

Amphetamine and methylphenidate are primarily indicated for narcolepsy (Table 3.2), idiopathic hypersomnia, and attention-deficit hyperactivity disorder (ADHD). However, other therapeutic uses are controversial because of their abuse potential. As a result, amphetamine is classified as a Schedule II substance and

TABLE 3.2 Current Pharmacological Treatment for Human Narcolepsy and Its Related Disorders

Compound	Usual Daily Doses (mg)	Half-Life (h)	Side Effects/Notes
Wake-promoting compounds:			
Sympathomimetic stimulants: d-amphetamine sulfate	5–60	16–30	Irritability, mood changes, headaches, palpitations, tremors, excessive sweating, insomnia
Methylphenidate HCl	10–60	~3	Same as amphetamines, less reduction of appetite or increase in blood pressure
Pemoline	20–115	11–13	Less sympathomimetic effect, milder stimulant, slower onset of action, occasionally produces liver toxicity
Nonamphetamine wake-promoting compounds: modafinil	100–400	11–14	No peripheral sympathomimetic action, headache, nausea

methylphenidate is classified as a Schedule III substance under the Controlled Substances Act of 1970.

Phenylisopropylamine (amphetamine) has a simple chemical structure resembling endogenous catecholamines (Fig. 3.3). The pharmacological effects of most amphetamine derivatives are isomer specific. D-Amphetamine, for example, is a far more potent stimulant than the L-derivative. In EEG studies, D-amphetamine is four times more potent in inducing wakefulness than L-amphetamine [65]; not all effects are, however, specific. For example, both enantiomers are equipotent at suppressing REM sleep in humans and rats [65] and at producing amphetamine psychosis. The relative effects of the D- and L- isomers of amphetamine on NE and DA transmission may explain some of these differences (for details, see Section 3.6.1.2).

Amphetamine-like compounds, such as methylphenidate, pemoline, and fencamfamin, are structurally similar to amphetamines; all compounds include a benzene core with an ethylamine group side chain (Fig. 3.3). Both methylphenidate and pemoline were commonly used for the treatment of EDS in narcolepsy, but pemoline has been withdrawn from the market in several countries because of liver toxicity (see Table 3.2). The most commonly used commercially available form of methylphenidate is a racemic mixture of both the D- and L- enantiomers, but D-methylphenidate

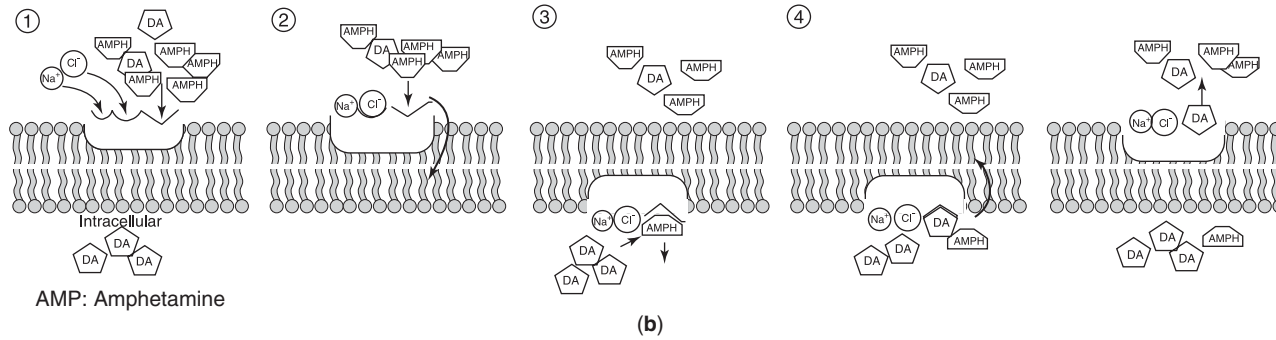

Figure 3.3 Chemical structures of amphetamine-like stimulants modafinil and caffeine (a xanthine derivative) as compared to DA and NE. (See color insert.)

mainly contributes to clinical effects, especially after oral administration. This is due to the fact that L-methylphenidate, but not D-methylphenidate, undergoes a significant first-pass metabolism (by deesterification to L-ritalinic acid).

Amphetamines are highly lipid soluble molecules that are well absorbed by the gastrointestinal tract. Peak levels are achieved approximately 2 h after oral administration, with rapid tissue distribution and brain penetration. Protein binding is highly variable, with an average volume of distribution (V_d) of 5 L/kg. The effects of amphetamine last approximately 6–10 h, with a half-life of 16–30 h. Both hepatic catabolism and renal excretion are involved in the inactivation of amphetamine. Methylphenidate is almost totally absorbed after oral administration, and peak levels are achieved approximately within 1–2 h, with rapid tissue distribution and brain penetration; slow release forms (peak levels of 5–6 h) are also available. Methylphenidate has low protein binding (15%) and is fairly short acting; the effects last approximately 4 h, with a half-life of 3 h. The primary means of clearance is through the urine, in which 90% is excreted.

3.6.1.1 Molecular Targets of Amphetamine Action. The molecular targets mediating amphetamine-like stimulant effects are complex and vary depending of the specific analog/isomer and the dose administered. Amphetamine per se increases catecholamine (DA and NE) release and inhibits reuptake. These effects are mediated by specific catecholamine transporters [66] (Fig. 3.4). The DA transporter (DAT) and the NE transporter (NET) have now been cloned and characterized. The DAT and NET proteins are about 620-amino-acid proteins with 12 putative membrane-spanning regions. Amphetamine derivatives inhibit the uptake and enhance the release of DA, NE, or both by interacting with these molecules. The DAT and NET normally move DA and NE, respectively, from the outside to the inside of the cell. This process is sodium dependent; sodium and chloride bind to the DA/NE transporter to immobilize it at the extracellular surface and to alter the conformation of the DA/NE binding site, thereby facilitating substrate binding. Substrate binding allows movement of the carrier to the intracellular surface of the neuronal membrane, driven by sodium concentration gradients. Interestingly, in the presence

Figure 3.4 (a) Effects of amphetamines at dopaminergic nerve terminal. (1) Amphetamine interacts with the DAT carrier to facilitate DA release from the cytoplasm through an exchange diffusion mechanism. At higher intracellular concentrations, amphetamine also (2) disrupts vesicular storage of DA and (3) inhibits the monoamine oxidase (MAO). Both these actions increase cytoplasmic DA concentrations. (4) Amphetamine also inhibits DA uptake by virtue of its binding to and transport by the DAT; DOPAC, dihydroxyphenylacetic acid. (b) Schematic model of exchange-diffusion process in relation to mode of action of amphetamines. (1) Sodium and chloride bind to the DAT to immobilize it at the extracellular surface. This alters the conformation of the DA binding site on the DAT to facilitate substrate binding. (2) Amphetamine, in competition with extracellular DA, binds to the transporter. Substrate binding allows the movement of the carrier to the intracellular surface of the neuronal membrane, driven by the sodium and amphetamine concentration gradients, resulting in a reversal of the flow of DA uptake. (3) Amphetamine dissociates from the transporter, making the binding site available to cytoplasmic DA. (4) DA binding to the transporter enables the movement of the transporter to the extracellular surface of the neuronal membrane, as driven by the favorable DA concentration gradient. (5) DA dissociates from the transporter, making the transporter available for amphetamine, and thus another cycle. (Adapted from [2].)

of some drugs such as amphetamine, the direction of transport appears to be reversed (Fig. 3.4). DA and NE are moved from the inside of the cell to the outside through a mechanism called exchange diffusion, which occurs at low doses (1–5 mg/kg) of amphetamine, and this mechanism is involved in the enhancement of catecholamine release by amphetamine. A recent in vitro experiment has shown that amphetamine transportation causes an inward current, and intracellular sodium ion becomes more available, thereby enhancing DAT-mediated reverse transport of DA.

At higher doses, other effects are involved. Moderate to high doses of amphetamine (> 5 mg/kg) interact with the vascular monoamine transporter 2 (VMAT2) (see [66]). The vesicularization of the monoamines (DA, NE, 5-HT, and histamine) in the central nervous system is dependent on VMAT2, and the VMAT2 regulates the size of the vesicular and cytosolic monoamine pools. Amphetamine is highly lipophilic and easily enters nerve terminals by diffusing across several mechanisms. It leads to a diffusion of the native monoamines out of the vesicles into the cytoplasm along a concentration gradient, and it acts as a physiological VMAT2 antagonist that releases the vascular DA/NE into the cytoplasm. These mechanisms, as well as the reverse transport and the blocking of reuptake of DA/NE by amphetamine, all lead to an increase in NE and DA synaptic concentrations (see [66]). High doses (higher than a clinical dose) of amphetamines are also shown to inhibit monoamine oxidase (MAO) and prevent catecholamine metabolism.

Various amphetamine derivatives have slightly different effects on all these systems. For example, methylphenidate also binds to the NET and DAT and weakly enhances catecholamine release but has less effect on the VMAT granular storage site than amphetamine. Similarly, D-amphetamine has proportionally more releasing effect on the DA versus the NE system when compared to L-amphetamine. Of note, other antidepressant medications acting on catecholamines, including both DA and NE (e.g., bupropion or mazindol), tend to exert their actions by simply blocking the reuptake mechanism.

3.6.1.2 Dopaminergic Neurotransmission and EEG Arousal. How amphetamines and other stimulants increase electroencephalogram (EEG) arousal has been explored using a canine model of the sleep disorder narcolepsy and DAT KO mice models. Canine narcolepsy is a naturally occurring animal model of the human disorder [7]. Similar to human patients, narcoleptic dogs are excessively sleepy (i.e., shorter sleep latency), have fragmented sleep patterns, and display cataplexy [7]. Although amphetamine-like compounds are well known to stimulate catecholaminergic transmission, the exact mechanism by which they promote EEG arousal is still uncertain. Stimulation of either or both adrenergic or dopaminergic transmission has been suggested to play a role.

In order to address this question, the effects of ligands specific for the DA (GBR12909, bupropion, and amineptine), NE (nisoxetine and desipramine), or both DA and NE (mazindol and nomifensine) transporters as well as amphetamine and a nonamphetamine stimulant, modafinil, were studied in narcoleptic and control Dobermans [67] (Fig. 3.5). DA uptake inhibitors such as GBR12909 and bupropion dose dependently increased EEG arousal in narcoleptic dogs, while nisoxetine and desipramine (two potent NE uptake inhibitors) had no effect on EEG arousal at doses which almost completely suppressed REM sleep and cataplexy (see [67]). Most strikingly, the EEG arousal potency of various DA uptake inhibitors correlated

tightly with in vitro DAT binding affinities (Fig. 3.5), while a reduction in REM sleep correlated with in vitro NET binding affinities [67]. These results strongly suggest that DA uptake inhibition is critical for the EEG arousal effects of these compounds.

Of note, D-amphetamine has a relatively low DAT binding affinity but potently (i.e., need for a low milligram-per-kilogram dose) promotes alertness (Fig. 3.5). It is also generally considered to be more efficacious (i.e., can produce more alertness at a higher dose) than pure DAT reuptake inhibitors in promoting wakefulness. However, as described earlier, D-amphetamine not only inhibits DA reuptake but also enhances DA release (at lower dose by exchange diffusion and at higher dose by antagonistic action against VMAT2) and inhibits monoamine oxidation to prevent DA metabolism. The DA releasing effects of amphetamine are likely to explain the unusually high potency and efficacy of amphetamine in promoting EEG arousal.

The effects of various amphetamine analogs (D-amphetamine, L-amphetamine, and L-methamphetamine) on EEG arousal and their in vivo effects on brain extracellular DA levels in narcoleptic dogs were compared [68] in order to further differentiate between the involvement of the DA and NE systems in the mode of action of amphetamine derivatives. In vitro studies have demonstrated that the potency and selectivity for enhancing release or inhibiting uptake of DA and NE vary between amphetamine analogs and isomers [69]. Amphetamine derivatives thus offer a unique opportunity to study the pharmacological control of alertness in vivo. Hartmann and Cravens previously reported that D-amphetamine is 4 times more potent in inducing EEG arousal than is L-amphetamine but that both enantiomers are equipotent at suppressing REM sleep in humans and rats [65]. Enantiomer-specific effects have also been reported with methamphetamine; L-methamphetamine is much less potent as a stimulant than either D-methamphetamine or D- or L-amphetamine (see [69]). Similarly, in canine narcolepsy, D-amphetamine is 3 times more potent than L-amphetamine and 12 times more potent than L-methamphetamine in increasing wakefulness and reducing SWS [68].

To further study what mediates these differences in potency, the effects of these amphetamine derivatives on DA release were examined in freely moving animals using in vivo microdialysis. Amphetamine derivatives (100 μ M) were perfused locally for 60 min through the dialysis probe implanted in the caudate of narcoleptic dogs [68]. The local perfusion of D-amphetamine raised DA levels 9 times above baseline. L-Amphetamine also increased DA levels by up to 7 times, but peak DA release was only obtained at the end of the 60-min perfusion period. L-Methamphetamine did not change DA levels under these conditions. These results suggest that D-amphetamine is more potent than L-amphetamine in increasing caudate DA levels, while L-methamphetamine had the least effect—in agreement with data obtained in other species using the same technique [69]. NE was also measured in the frontal cortex during perfusion of D-amphetamine, L-amphetamine, and L-methamphetamine. Although all compounds increased NE efflux, no significant difference in potency was detected among the three analogs.

The fact that the potency of amphetamine derivatives on EEG arousal correlates with effects on DA efflux in the caudate of narcoleptic dogs further suggests that the enhancement of DA transmission by presynaptic modulation mediates the wake-promoting effects of amphetamine analogs. This result is also consistent with data obtained with DAT blockers (see Fig. 3.5). Considering the fact that other amphetamine-like stimulants (such as methylphenidate and pemoline) also inhibit

DA uptake and enhance release of DA, the presynaptic enhancement of DA transmission is likely to be the key pharmacological property mediating wake promotion for all amphetamines and amphetamine-like stimulants.

The role of the DA system in sleep regulation was further assessed using mice lacking the DAT gene. Consistent with a role of DA in the regulation of wakefulness, these animals have reduced non-REM sleep time and increased wakefulness

consolidation (independently from locomotor effects) [70]. DAT KO mice have also proven to be a powerful tool to help dissect the molecular mechanisms mediating the effects of nonselective monoaminergic compounds. Using these animals, DAT was shown to be involved in mediating locomotor activation after amphetamine and cocaine administration. Indeed, no locomotor stimulation is observed in these mice after cocaine or amphetamine. Interestingly, NET KO mice are more sensitive to the locomotor stimulation of amphetamine, suggesting that NET may play a feedback control role on amphetamine-induced dopaminergic effects [71]. With regard to sleep, the most striking finding was that DAT KO mice were completely unresponsive to the wake-promoting effects of methamphetamine, GBR12909 (a selective DAT blocker), and modafinil. These results further confirm the critical role of DAT in mediating the wake-promoting effects of amphetamines and modafinil (Fig. 3.5) [70] (see also Section 3.7.1). Interestingly, DAT KO animals were also found to be more sensitive to caffeine [70], suggesting functional interactions between adenosine and DA systems in the control of sleep/wakefulness (see also Section 3.7.5).

3.6.1.3 Anatomical Substrates of Dopaminergic Effects. Anatomical studies have demonstrated two major subdivisions of the ascending DA projections from mesencephalic DA nuclei (VTA, SN, and retrorubral [A8]): (1) The mesostriatal system originates in the SN and retrorubral nucleus and terminates in the dorsal striatum (principally the caudate and putamen) [72]. (2) The mesolimbocortical DA system consists of the mesocortical and mesolimbic DA systems. The mesocortical

Figure 3.5 (a) Effects of various DA and NE uptake inhibitors and amphetamine-like stimulants on EEG arousal of narcoleptic dogs. The effects of various compounds on daytime sleepiness was studied using 4-h daytime polygraphic recordings (10:00 to 14:00) in four to five narcoleptic animals. Two doses were studied for each compound. All DA uptake inhibitors and CNS stimulants dose-dependently increased EEG arousal and reduced slow-wave sleep (SWS) when compared to vehicle treatment. In contrast, nisoxetine and desipramine, two potent NE uptake inhibitors, had no significant effect on EEG arousal at doses that completely suppressed cataplexy. Compounds with both adrenergic and dopaminergic effects (nomifensine, mazindol, D-amphetamine) were active on both EEG arousal and cataplexy. The effects of the two doses studied for each stimulant were used to approximate a dose–response curve; the drug dose that increased the time spent in wakefulness by 40% above baseline (vehicle session) was estimated for each compound. The order of potency of the compounds obtained was mazindol > (amphetamine) > nomifensine > GBR12 909 > amineptine > (modafinil) > bupropion. (b) Correlation between in vivo EEG arousal effects and in vitro DA transporter binding affinities. In vitro DAT binding was performed using [³H]-WIN 35,428 onto canine caudate membranes. Affinity for the various DA uptake inhibitors tested varied widely between 6.5 and 3.3 mM. In addition, it was also found that both amphetamine and modafinil have a low but significant affinity (same range as amineptine) for the DAT. A significant correlation between in vivo and in vitro effects was observed for all five DA uptake inhibitors and modafinil. Amphetamine, which had potent EEG arousal effects, has a relatively low DAT binding affinity, suggesting that other mechanisms, most probably monoamine-releasing effects or monoamine oxidase inhibition, are also involved. In contrast, there was no significant correlation between in vivo EEG arousal effects and in vitro NE transporter binding affinities for DA and NE uptake inhibitors. These results suggest that presynaptic enhancement of DA transmission is the key pharmacological property mediating the EEG arousal effects of most wake-promoting CNS stimulants. (Adapted from [67].)

system originates in the VTA and the medial SN and terminates in the limbic cortex (medial prefrontal, anterior cingulate, and entorhinal cortices). Interestingly, DA reuptake is of physiological importance for the elimination of DA in cortical hemispheres, limbic forebrain, and striatum but not in midbrain DA neurons. It is thus possible that DA uptake inhibitors (and amphetamine and modafinil) act mostly on DA terminals of the cortical hemispheres, limbic forebrain, and striatum to induce wakefulness. Local perfusion experiments of DA compounds in rats and canine narcolepsy have suggested that the VTA, but not the SN, is critically involved in the regulation of EEG arousal [73]. DA terminals of the mesolimbocortical DA system may thus be important in mediating wakefulness after DA-related CNS stimulant coadministration.

3.6.1.4 Adverse Effects of Amphetamine and Amphetamine-Like Compounds. As described repeatedly, amphetamine releases not only DA but also NE. NE indirectly stimulates α - and β -adrenergic receptors, a profile common to all indirectly acting sympathomimetic compounds. This results in significant cardiovascular effects. α -Adrenergic stimulation produces vasoconstriction, thereby increasing both systolic and diastolic blood pressure. Heart rate may slow down slightly in reflex (this effect is more pronounced than indirect β -adrenergic stimulation on heart rate at low dose). Smooth muscles respond to amphetamine as they do with other sympathomimetic drugs. There is a contractile effect on the urinary bladder sphincter—an effect that has been used in treating enuresis and incontinence.

Other acute side effects include mild gastrointestinal disturbance, anorexia, dryness of the mouth, tachycardia, cardiac arrhythmias, insomnia, restlessness, headaches, palpitations, dizziness, and vasomotor disturbances. Also, agitation, confusion, dysphoria, apprehension, and delirium may occur. Other documented side effects include flushing, pallor, excessive sweating, and muscular pains. Tiredness and sleepiness as well as lethargy and listlessness may also occur when the effects wear off (in addition to a mild mood depression). For common side effects of CNS stimulant drugs in narcoleptics, refer to Table 3.2.

Common side effects occurring during long-term treatment in narcolepsy include irritability, headache, ill temper, and profuse sweating (reported by over one-third of subjects). Other less common side effects include anorexia, gastric discomfort, nausea, talkativeness, insomnia, orofacial dyskinesia, nervousness, palpitations, muscle jerking, chorea, and tremor. Psychiatric symptoms such as delusions or hallucinations may also occur but are rather rare in narcoleptic patients that receive amphetamine. Methamphetamine is more frequently associated with central nervous system complications because of its higher toxicity and central penetrance.

The side-effect profile of methylphenidate is similar to that of amphetamine but is less severe and includes nervousness, insomnia, and anorexia as well as dose-related systemic effects such as increased heart rate and blood pressure. Methylphenidate overdose may lead to seizures, dysrhythmias, and hyperthermia.

3.6.1.5 Drug Interactions with Amphetamine and Amphetamine-Like Compounds. Drug interactions with amphetamine and methylphenidate are generally pharmacodynamic/neurochemical in nature. A small portion of the metabolism of amphetamine and methylphenidate occurs via the cytochrome P450 2D6, and drugs that inhibit 2D6 metabolism can theoretically increase plasma levels of amphetamine.

TABLE 3.3 Antidepressants Currently Used as Anticatataptic Agents

Antidepressants			
Compound	Usual Daily Doses (mg)	Half-life (h)	Notes/Side Effects
Tricyclics			
Imipramine	10–100	5–30	Dry mouth, anorexia, sweating, constipation, drowsiness
Desipramine	25–200	10–30	(NE » 5-HT > DA) A desmethyl metabolite of imipramine, effects and side effects similar to those of imipramine
Protriptyline	5–60	55–200	(NE > 5-HT > DA) Reported to improve vigilance measures anticholinergic effects
Clomipramine	10–150	15–60	(5-HT > NE » DA) Digestive problem, dry mouth, sweating, tiredness, impotence; anticholinergic effects; desmethyl-clomipramine (NE » 5-HT > DA) is an active metabolite.
SSRIs			
Fluoxetine	20–60	24–72	No anticholinergic or antihistaminergic effects, good anticatataptic effect but less potent than clomipramine; Active metabolite norfluoxetine has more adrenergic effects
Fluvoxamine	50–300	15	No active metabolite, pharmacological profile similar to fluoxetine, less active than clomipramine, gastrointestinal side effects
SNRIs			
Venlafaxine	150–375	4	New serotonergic and adrenergic uptake blocker; no anticholinergic effects, effective on cataplexy and sleepiness, nausea
Milnacipran	30–50	8	New serotonergic and adrenergic uptake blocker; no anticholinergic or antihistaminergic effects, effective on cataplexy
Atomoxetine NRI	40–60 ^a	5.2	Normally indicated for ADHD

Abbreviations: SSRI, selective serotonin reuptake blocker; NSRI, norepinephrine/serotonin reuptake inhibitor; NRI, norepinephrine reuptake inhibitor. Reboxetine is another NRI but is not available in the U.S.

^aDoses for treatments for ADHD suggested to start with smaller doses for anticatataptic treatment. GABA (GHB, sodium oxybate) is also reported to be effective on cataplexy and may act via GABA_B or via specific GHB receptors. Reduces dopamine release.

This is however rarely a significant problem with therapeutic doses. Tricyclic drugs inhibit the metabolism of amphetamine and amphetamine-like stimulants and enhance their behavioral effects [74]. However, in practice, amphetamine, 10–16 mg (and also methylphenidate, 10–60 mg, and mazindol, 2–12 mg), has been given safely with imipramine and clomipramine and at a dose range of 10–100 mg to treat narcolepsy–cataplexy [75]. The dosage of amphetamine required to control EDS in narcolepsy may be reduced by one-third through the simultaneous use of tricyclic drugs. MAO_A inhibitors (e.g., nialamide, pargyline, and tranylcypromine), inhibit the removal of amphetamine by the liver and greatly potentiate the behavioral effects of amphetamine. Consequently, coadministration of MAO inhibitors (MAOIs) and amphetamine derivatives is generally contraindicated.

3.7 NONAMPHETAMINE STIMULANTS

3.7.1 Modafinil

Modafinil (2-[(diphenylmethyl)sulfinyl]acetamide) (Fig. 3.3) is a chemically unique compound developed in France. Modafinil has been available in France since 1984 on a compassionate mode and was approved in France in 1992. Modafinil has recently been approved in the United States for the treatment of narcolepsy, idiopathic hypersomnia, shiftwork disorder, and residual sleepiness in treated patients with the sleep apnea syndrome. Modafinil is a primary metabolite of adrafinil, a vigilance-promoting compound discovered in France in 1974. The kinetic study of adrafinil led to the identification of modafinil in 1976. Modafinil lacks adrafinil's terminal amide hydroxy group (Fig. 3.3) and is better tolerated.

Modafinil is rapidly absorbed but slowly cleared. It has fairly high protein binding and a V_d of 0.8 L/kg. Its half-life is 11–14 h. Up to 60% of modafinil is converted to modafinil acid and modafinil sulfone, both of which are inactive metabolites. Metabolism primarily occurs via cytochrome P450 3A4/5, but the compound has also been reported to induce cytochrome P450 2C 19 *in vitro*. Modafinil is currently available as a racemic mixture of two active isomers. In humans, the D-isomer is cleared three times faster than the L-isomer, and females clear modafinil faster than males. The two isomers may also have slightly different pharmacodynamic properties and the longer acting isomer is currently under development.

Modafinil is one of the few compounds that have been specifically developed for the treatment of narcolepsy. Early trials include a clinical trial by Bastujji and Jouvet [76] in 1988, and the first double-blind multicenter trial in three French centers and one Canadian center in 1994 [77] have shown that 100–300 mg modafinil is effective in improving daytime sleepiness in narcolepsy and hypersomnia without interfering with nocturnal sleep but has limited efficacy on cataplexy and other symptoms of abnormal REM sleep. Modafinil is well tolerated and the most frequent reported side effects are headache, nausea, rhinitis, and nervousity (in descending order). Early clinical trials in French and Canadian pharmacological experiments in canine narcolepsy also demonstrated that modafinil has no effects on cataplexy, while it significantly increases time spent in wakefulness [78]. A recent double-blind trial in 18 centers in the United States on 283 narcoleptic subjects revealed that 200 and 400 mg of modafinil significantly reduced EDS and improved patients' overall clinical

condition. Modafinil is well tolerated and the most frequent reported side effects are headache and nausea [79].

Several factors make modafinil an attractive alternative to amphetamine-like stimulants. First, animal studies suggest that the compound does not affect blood pressure as much as amphetamines do; only high doses (800 mg) have been found to be associated with higher rates of tachycardia and hypertension. This suggests that modafinil might be useful for patients with a heart condition or high blood pressure. Second, data obtained to date suggest that tolerance and dependence is limited with this compound [76], although a recent animal study suggests cocaine-like discriminative stimulus and reinforcing effects of modafinil in rats and monkeys, respectively. Third, modafinil also has little effect on the neuroendocrine system. A comparison of healthy volunteers who were sleep deprived for 36 h versus those who received modafinil during sleep deprivation found no difference in cortisol, melatonin, or growth hormone levels. Fourth, clinical experience suggests that the alerting effects of modafinil might be qualitatively different from those observed with amphetamine [76]. In general, patients feel less irritable and/or agitated with modafinil than with amphetamines [76] and do not experience severe rebound hypersomnolence once modafinil is eliminated. This differential profile is substantiated by animal experiments. In rats and dogs, modafinil does not increase locomotion beyond the effect expected in association with increased wakefulness [78, 80]. Similarly, modafinil acutely decreases both REM and non-REM sleep in rats for up to 5–6 h, but the effect is not followed by a rebound hypersomnolence. This profile contrasts with the intense sleep recovery seen following amphetamine-induced wakefulness. Considering the many advantages of modafinil over amphetamine treatment (fewer cardiovascular side effects, lower abuse potential, tolerance, and less rebound sleepiness when the drug effects are waning), modafinil has replaced amphetamine-like stimulants as a first-line treatment for EDS.

Current indications for modafinil include narcolepsy and idiopathic hypersomnia, and it has recently been approved by the Food and Drug Administration (FDA) for the treatment of shift work disorder and residual sleepiness in treated sleep apnea patients [generally with continuous positive airway pressure (CPAP)]. There are several reports suggesting that modafinil is also effective for treatment of ADHD, fatigue in multiple sclerosis, and EDS in myotonic dystrophy or Prader–Willi syndrome. Modafinil is also being used in the treatment of recurrent hypersomnia.

The mechanism of action of modafinil is highly debated. An interaction and/or involvement of adrenergic α_1 systems was initially suggested by the ability of the α_1 antagonist prazosin to antagonize modafinil-induced increases in motor activity in mice [81] and wakefulness in cats [82]. However, modafinil does not bind to α_1 receptors *ex vivo* ($K_i > 10^{-3}$ M, obtained from prazosin binding using canine cortex) (see [78]). Furthermore, previous studies in the canine model of narcolepsy have shown that adrenergic α_1 agonists potently reduce cataplexy with a significant acute hypertensive effect. The fact that modafinil has no anticataplectic activity and lacks hypertensive effects rather suggests that its alerting properties are not derived from adrenergic α_1 stimulation.

A serotonergic 5-HT₂ receptor-mediated change in γ -aminobutyric acid (GABA)–ergic transmission was next suggested [83]. Modafinil increases 5-HT metabolism in the striatum and reduces GABA flow to the cortex [83]. The effect on GABA release is blocked by ketanserin (a 5-HT₂ antagonist) but not by prazosin [83]. Furthermore,

muscimol, a GABAergic agonist, blocks the effect of modafinil on wakefulness in cats [82]. Although a serotonergic–GABAergic interaction may be involved in the mode of action of modafinil, the effects described may be indirect and additional work is needed to substantiate this hypothesis. As for the 5-HT₂ receptor, modafinil does not bind to serotonergic receptors *in vitro*.

In the canine model of narcolepsy, it was observed that selective dopaminergic reuptake inhibitors have no effect on canine cataplexy but potently promote wakefulness (Fig. 3.5) [67]. Modafinil had a similar profile, and it was subsequently found that modafinil has a low but selective affinity for the DAT [67]. A lack of wake-promoting effects of modafinil (as well as amphetamine) in DAT KO mice clearly demonstrates that an intact DAT molecule is required for mediating modafinil's arousal effect [70].

Other investigators have shown, however, that modafinil can be distinguished pharmacologically from most other compounds with presynaptic dopaminergic activity. For example, modafinil does not produce stereotypic behavior at high doses. Additionally, agents that inhibit dopaminergic function such as D₁ blockers, D₂ blockers, and tyrosine hydroxylase blockers have no effect on modafinil's locomotor-enhancing effects in mice. Finally, an *in vitro* voltammetry study found that modafinil did not increase the catechol oxidation peak height (an indirect measure of dopaminergic activity), suggesting a lack of presynaptic dopaminergic involvement of modafinil activity. Ferraro et al. [84], however, reported that systemic administration of modafinil (30–300 mg/kg) dose dependently increased DA release in the nucleus accumbens in rats, but these authors claimed that the DA-releasing action of modafinil was most likely secondary to its ability to reduce local GABAergic transmission.

Not only is the exact molecular target of modafinil action uncertain, but also there is much debate regarding modafinil's neuroanatomical site of action. Anatomical studies coupled with functional markers of neuronal activity (i.e., the immediate early gene product Fos) have been used to determine activation patterns induced by modafinil in comparison with other stimulants [85]. In cats, amphetamine and methylphenidate induce c-Fos throughout the cortex, striatum, and other brain regions. In contrast, modafinil induces a much more restricted pattern of neuronal activation, with marked expression of c-Fos in neurons of the anterior hypothalamus area and suprachiasmatic nuclei—brain regions that have been implicated in sleep and circadian regulation [85]. Modafinil also increases c-Fos expression in hypocretin cells [35, 86] and histaminergic cells of the tuberomammillary nucleus; these effects have been suggested to mediate the wake-promoting effects of modafinil. At higher doses, the striatum and cingulate cortex are also activated [86]. Of note, however, it is likely that the stimulation of hypocretin cells is not essential to induce wakefulness since both *hcrtr2* mutated canine narcolepsy and hypocretin-ligand-deficient human narcolepsy (found in 90% of narcolepsy–cataplexy patients) respond well to modafinil treatment. More likely, activation of these cell groups is secondary to the expression of increased wakefulness, as c-Fos expression in these cell groups increases in naturally occurring wakefulness.

Gallopini et al. recently reported that modafinil inhibits the sleep-active neurons of the ventrolateral preoptic nucleus (VLPO; a sleep-promoting network of neurons) by facilitating adrenergic neurotransmission [87]. In this study, modafinil potentiated the inhibitory effects of NE on VLPO neurons in a slice preparation. Surprisingly,

modafinil did not potentiate the inhibitory effects of DA or 5-HT on VLPO neurons. Nisoxetine, a potent NET inhibitor with low affinity to DAT [67], had a similar effect and the response to the two drugs was not addictive, suggesting they might work through the same biochemical pathways. Since modafinil does not bind to the NET [67] and NE uptake inhibitors do not possess strong wake-promoting effects, modafinil may modulate NE/DA uptake mechanisms through novel mechanisms. In this case, modafinil may work on both the DA and NE system to promote wakefulness, and adrenergic–DAT interactions may be involved. Of note, however, very high modafinil concentrations (generally 200 μ M, the maximum that can be dissolved) were used in this study *in vitro*, and it may also be that at this very high dose small effects on adrenergic uptake, undetectable with the usual radio receptor binding assays, could occur.

Further studies of the action of modafinil will be needed to clarify the above discrepancies regarding its modes of action and may lead to new and interesting insights into the mode of action of stimulant medications in general.

3.7.2 Mazindol

Mazindol (2–8 mg daily), a sympathomimetic anorectic agent, is rarely used in the United States. At these doses, mazindol produces central stimulation, a reduction in appetite, and an increase in alertness but has little or no effect on mood or the cardiovascular system. Mazindol is a weak releasing agent for DA that also blocks both DA and NE reuptake. Mazindol has a high affinity for the DA and NE transporters (see [67]), yet interestingly this compound has a low abuse potential. It is effective for the treatment of both EDS and cataplexy in humans [88] and in canine narcolepsy [89], possibly due to its dual dopaminergic and noradrenergic effects [67]. Narcoleptics are relatively well tolerated to mazindol, and reported side effects are insomnia, headache, anorexia, constipation, chest discomfort, and delayed menstruation, but drug tolerance may occur in some patients. However, higher doses of mazindol are reported to cause other side effects, including gastrointestinal discomfort, nervousness, dry mouth, nausea, urinary retention, vomiting, tremor, and angioneurotic edema. Therefore, mazindol may not be recommended for treatment of severe narcoleptic subjects that require large doses.

3.7.3 Bupropion

Bupropion is a DA reuptake inhibitor that may be useful for the treatment of EDS associated with narcolepsy (100 mg t.i.d.) [67, 90]. It may be especially useful in cases associated with atypical depression [90]. Bupropion was synthesized in 1966 by a group seeking new antidepressants chemically related to tricyclic antidepressants but without any significant sympathomimetic, cholinolytic, or MAOI properties. Bupropion is classified as a monocyclic phenylbutylamine of the aminoketone group. It selectively blocks DA uptake and is 6 times more potent than imipramine and 19 times more potent than amitriptyline in blocking DA reuptake. The selectivity of bupropion for the DAT is not absolute. Bupropion is a weak competitive inhibitor of NE reuptake (65-fold less potent than imipramine), and very limited serotonergic effects are also observed (200-fold less potent than imipramine). Bupropion is generally well tolerated, and the most commonly reported side effects include

headache, nausea, dry mouth, and insomnia. Convulsion is a dose-dependent risk of bupropion (0.1% at 100–300 mg and 0.4% at 400 mg).

3.7.4 Selegiline (L-Deprenyl)

Selegiline is a methamphetamine derivative and a potent, irreversible MAO_B selective inhibitor primarily used for the treatment of Parkinson's disease. Low doses of selegiline do not necessitate dietary restriction as usually required with other irreversible MAOIs. Ten milligrams of selegiline daily has no effect on the symptoms of narcolepsy, but 20–30 mg improves alertness and mood and reduces cataplexy, an effect comparable to D-amphetamine at the same dose [91]. Selegiline may be an interesting alternative to the use of more classical stimulants, as its potential for abuse has been reported to be very low.

The fact that this compound is often considered as a simple MAO_B inhibitor rather than an amphetamine precursor deserves special mention. Selegiline does not only inhibit MAO_B irreversibly, it also metabolizes into amphetamine (20–60% in urine) and methamphetamine (9–30% in urine). In the canine model of narcolepsy, selegiline (2 mg/kg p.o.) was demonstrated to be an effective anticataplectic agent, but this effect was found to be mediated by its amphetamine metabolites rather than via MAO_B inhibition [92]. Several trials in human narcolepsy have demonstrated a good therapeutic efficacy of selegiline on both sleepiness and cataplexy with relatively few side effects [91, 93], but this efficacy is also likely to be partially mediated by amphetamine metabolites.

3.7.5 Caffeine

Caffeine may be the most popular and widely consumed CNS stimulant in the world. An average cup of coffee contains 50–150 mg of caffeine. Tea, cola drinks, chocolate, and cocoa all contain significant amounts of caffeine. Caffeine can also be bought over the counter (OTC) (Nodoz, 100 mg caffeine; Vivarin, 200 mg caffeine) and is commonly used by narcoleptic patients prior to diagnosis.

Taken orally, caffeine is absorbed rapidly. The half-life of caffeine is 3.5–5 h. The behavioral effects of caffeine include increased mental alertness, a faster and clearer flow of thought, wakefulness, and restlessness. Fatigue is reduced and sleep onset delayed [94]. The physical effects of caffeine include palpitations, hypertension, increased gastric acid secretion, and increased urine output [94]. Heavy consumption (12 or more cups a day, or 1.5 g of caffeine) causes agitation, anxiety, tremors, rapid breathing, and insomnia.

Caffeine is a xanthine derivative. The mechanism of action of caffeine on wakefulness involves nonspecific adenosine receptor antagonism. Adenosine is an endogenous sleep-promoting substance with neuronal inhibitory effects. In animals, sleep can be induced after administration of metabolically stable adenosine analogs with adenosine A₁ receptors (A₁R) or A_{2A} receptors (A_{2A}R) agonistic properties, such as *N*6-L-(phenylisopropyl)-adenosine, adenosine-5'-*N*-ethylcarboxamide, and cyclohexyladenosine [95]. Adenosine content is increased in the basal forebrain after sleep deprivation. Adenosine has thus been proposed to be a sleep-inducing substance accumulating in the brain during prolonged wakefulness [96].

Most studies in the area of sleep and adenosinergic effects have focused on A1R-mediated effects. The rationale for this focus is that A1R is widely distributed in the CNS, whereas A2AR is discretely localized in the striatum, nucleus accumbens, and olfactory bulb. Interestingly, sleep–wake patterns and response to sleep deprivation were recently examined in A1R KO mice and found to be generally unaltered, suggesting that the constitutional lack of A1R does not prevent homeostatic regulation of sleep. In contrast, the sleep inhibitory effects of 8-cyclopentyltheophylline (a selective A1R antagonist) were abolished in these animals, indicating A1R mediation of stimulant effects with this compound.

3.8 FUTURE STIMULANT TREATMENTS

It is now revealed that human narcolepsy is caused by a dramatic decrease in hypocretin levels in the brain and CSF. This raises the possibility that hypocretin-based stimulant therapies may be designed in the future. Recent experiments in canine narcolepsy (receptor mutated and ligand deficient) suggest that stable and centrally active hypocretin analogs (possibly nonpeptide synthetic hypocretin ligands) will need to be developed in order to be effective peripherally [97]. This is also substantiated by a recent study that found normalization of sleep/wake patterns and behavioral arrest episodes (equivalent to cataplexy and REM sleep onset) in orexin/hypocretin—deficient mice models supplemented by central administration of hypocretin-1 [98] (see Section 3.12).

Another potential drug development in the area of wake promotion is with histaminergic compounds. Histamine has long been implicated in the control of vigilance, and H₁ antagonists are strongly sedative. The downstream effects of hypocretins on the histaminergic system (*Hcrtr2* excitatory effects) are likely to be important in mediating the wake-promoting properties of hypocretin [49]. In fact, brain histamine and CSF histamine contents are reduced in narcoleptic subjects [52, 99]. Although centrally injected histamine or histaminergic H₁ agonists promote wakefulness, systemic administrations of these compounds induce various unacceptable side effects via peripheral H₁ receptor stimulation. In contrast, the histaminergic H₃ receptors are regarded as inhibitory autoreceptors and are enriched in the CNS. H₃ antagonists enhance wakefulness in normal rats and cats [100] and in narcoleptic mice models [101]. Histaminergic H₃ antagonists might be useful as wake-promoting compounds for the treatment of EDS or as cognitive enhancers and are under study in several pharmaceutical companies.

Another possible area with less current pharmaceutical interest is the use of thyrotropin-releasing hormone (TRH) direct or indirect agonists. TRH itself is a small peptide which penetrates the blood–brain barrier at very high doses. Small molecules with agonistic properties and increased blood–brain barrier penetration (i.e., CG3703, CG3509, or TA0910) have been developed, partially due to the small nature of the starting peptide [102]. TRH (at the high dose of several milligrams per kilogram) and TRH agonists increase alertness and have been shown to be wake promoting and antiepileptic in the narcoleptic canine model [103, 104], and it has excitatory effects on motoneurons [105]. Initial studies had demonstrated that TRH enhances DA and NE neurotransmission [106, 107], and these properties may partially contribute to the wake-promoting and antiepileptic effects of TRH.

Interestingly, recent studies have suggested that TRH may promote wakefulness by directly interacting with the thalamocortical network: TRH itself and TRH receptor type 2 are abundant in the reticular thalamic nucleus [108]. The local application of TRH in the thalamus abolishes spindle wave activity [109], and in the slice preparations, TRH depolarized thalamocortical and reticular/perigeniculate neurons by inhibition of leak K^+ conductance [109].

Other pathways with possible applications in the development of novel stimulant medications include the adenosinergic system (see above), the adrenergic system (e.g., some NE reuptake inhibitors), the GABAergic system (e.g., inverse benzodiazepine agonists), and the glutamatergic system (ampakines) (see [7]).

3.9 PHARMACOLOGICAL TREATMENT OF CATAPLEXY

3.9.1 Historical Overview of Antidepressants

Since the 1960s, it has been known that imipramine is very effective for reducing cataplexy [110]. Together with protriptyline and clomipramine, these tricyclic antidepressants are still the most commonly used anticataplectic agents (Table 3.3).

Antidepressants are drugs that are effective for treating depression and are represented by a diverse group of chemical structures. Many hypotheses about how these antidepressants work exist, and usually these theories involve biogenic amine neurotransmitters, especially NE and 5-HT [111].

Of the many antidepressants, some of the first types discovered and, up until about 10 years ago, the most widely prescribed were the tricyclics, so named because of the three fused rings in the structure. The prototype of this class of compound, imipramine, was initially synthesized for use as an antihistamine (H_1) but was discovered to have antidepressant properties as the result of astute clinical observations on depressed schizophrenic patients [111]. Imipramine was selected for a trial in schizophrenia because of its close structural similarity to chlorpromazine. This finding led to the study of imipramine in clinical trials in depressed patients which subsequently proved its efficacy as an antidepressant [111].

Another class of antidepressants, the MAOIs, was introduced in the 1950s because of observations in both the clinic and laboratory [112]. The first compound of this group to be tested and proven effective as an antidepressant was iproniazid, an antituberculosis drug. This research began after scientists observed that iproniazid caused euphoria and elation in some patients treated for tuberculosis and that it reversed the apparent sedation caused by the drug reserpine in laboratory animals. MAOIs are used much less frequently than other types of antidepressants because of the “cheese reaction,” a marked and potentially fatal increase in blood pressure that can occur when a patient being treated with one of these drugs ingests foods with high tyramine content (such as aged cheese, bananas, smoked and pickled fish, fermented sausages, and red wine, to list a few) [112]. The excess tyramine, which cannot be degraded by MAO, displaces neuronal stores of catecholamines (e.g., NE) that ultimately increase blood pressure. Consequently, patients taking MAOIs are required to be on a tyramine-free diet and must also avoid the use of sympathomimetic stimulants.

Shortly after the discovery of tricyclic antidepressants, it was shown that these drugs acutely blocked reuptake of both NE and 5-HT by the nerve ending [111]. In general, tertiary amine tricyclic antidepressants, such as imipramine or clomipramine, were potent blockers of 5-HT reuptake but weak blockers of NE transport, whereas the converse seemed true for the secondary amine compounds [113]. It was also shown that MAOIs increase brain levels of catecholamines and 5-HT by preventing their degradation [112]. Thus, it was thought that the therapeutic effect of the antidepressant was due to increased duration of elevated levels of monoamines in the synaptic cleft (i.e., the monoamine hypothesis), but the exact mechanisms of the action of antidepressants on depressive symptoms are not known [111]. One of the complex issues is the fact that the mood-elevating effect of antidepressants does not become apparent until at least 7–10 days to several weeks after treatment has started; longer term mechanisms need to be considered. This sharply contrasts to an immediate occurrence of antiepileptic effects by these compounds when they are used in narcoleptic patients [7].

Most classical tricyclics also have the ability to block several neurotransmitter receptors, such as at histaminergic H_1 , muscarinic acetylcholinergic, α_1 -adrenergic, and serotonergic 5-HT_{2A} receptors [111]. These pharmacological effects occur immediately and are probably not related to its major mode of action but underlie various adverse effects. For example, muscarinic receptor blockade can cause dry mouth and constipation, and histamine H_1 receptor antagonism can cause sedation and drowsiness. Some antidepressants (such as the tricyclic antidepressant doxepin) have such high affinity for the H_1 receptor that they are among the most potent histamine H_1 antagonists available. Thus, doxepin is also used for the treatment of allergy and certain dermatological problems.

3.9.2 Tricyclic (First-Generation) Antidepressants

First-generation tricyclic antidepressants, such as imipramine, protriptyline, and clomipramine, potentially reduce cataplexy in many subjects and therefore are still the most commonly used antiepileptic agents (Table 3.3). Similar to the situation seen in patients with depression, the use of tricyclic antidepressants in the treatment of cataplexy is, however, also hampered by a number of problems. The first is the relatively poor side-effect profile of most tricyclic compounds. These are mostly due to their anticholinergic properties, thus leading to dry mouth (and associated dental problems), tachycardia, urinary retention, constipation, and blurred vision (see Table 3.3). This profile was initially thought to be involved in antiepileptic effects of these tricyclics. However, animal experiments as well as findings with newer antidepressants in human narcolepsy suggest that this property is not required for the antiepileptic property of antidepressants. Additional side effects are weight gain, sexual dysfunction (impotence and/or delayed orgasm), tremors, antihistamine effects leading to sedation, and occasionally orthostatic hypotension due to the α_1 -adrenergic blockade of some compounds. Nighttime sleep might also become more disturbed due to increased muscle tone and leg movements [60].

As described earlier, the cardinal pharmacological property of tricyclic antidepressants is their ability to inhibit the reuptake of NE (and epinephrine) and 5-HT [111]. The degree of reuptake inhibition of NE and 5-HT is quite variable depending on the compound and on the existence of active metabolites (mostly active on

adrenergic reuptake). Active metabolites often have longer half-lives and tend to accumulate during chronic drug administration. The metabolic half-lives of these compounds also vary among individuals. Additionally, some tricyclic compounds (such as protriptyline), are also weak DA reuptake inhibitors [111]. Thus, it is not simple to conclude which pharmacological property is important for the anticataplectic effects in humans.

3.9.3 Second- to Third-Generation Antidepressants

The newer second-generation antidepressants usually are more selective at blocking the reuptake of 5-HT over NE. This has led to the concept of the serotonin-selective reuptake inhibitor (SSRI) [114]. The first of this group and the most widely prescribed until recently was fluoxetine, which was first marketed in the United States in 1988. The introduction of newer antidepressants with selective serotonergic reuptake inhibition properties and no anticholinergic effects (i.e., SSRIs), (such as fluoxetine, fluvoxamine, paroxetine, sertraline, femoxamine, zimelidine, and citalopram) has raised hope that the control of cataplexy can be achieved with fewer side effects. In general, however, clinicians have been less impressed with the anticataplectic effects of the SSRIs than those of classical tricyclics [115, 116]. Among these compounds, fluoxetine at the 20- to 60-mg dose is a viable alternative to tricyclic compounds [115]. Fluoxetine has a good side-effect profile and induces anorexia rather than weight gain, a significant advantage for some patients.

Another compound, venlafaxine, is marketed as a 5-HT and NE reuptake inhibitor (SNRI) antidepressant, and it reduced cataplexy and sleepiness in a small pilot study. Another SNRI, milnacipran, is available in some European countries and Japan, and this compound reduces cataplexy in humans and canines (experiments in progress). A selective NE blocker, atomoxetine (developed under the name of tomoxetine), was also introduced in the U.S. market and used for the treatment of ADHD. Yet another selective NE blocker, reboxetine, is only available in some European countries. Although no published data are yet available, it may be interesting to evaluate the anticataplectic effects of selective NE blockers such as atomoxetine and reboxetine.

Because the newer second-generation drugs usually have lower affinities for the above-mentioned receptors, they are also less likely to cause the adverse effects commonly seen with the older antidepressants [114].

3.9.4 Mechanisms of Action of Tricyclic Anticataplectics

Neuropharmacological understandings of cataplexy also have been greatly facilitated using these canine models [7]. Since cataplexy can be easily elicited by food or play and the severity of cataplexy can be quantified by a simple behavioral assay (i.e., food-elicited cataplexy test), these animals have been intensively used for evaluating anticataplectic effects of various compounds [7].

Although the mechanism for the induction of cataplexy is not identical to that for REM sleep, both likely share common physiological and pharmacological mechanisms, especially for the executive systems for muscle atonia. Thus, the understanding of the pharmacological control of REM sleep is essential to the understanding of cataplexy.

The importance of increased cholinergic activity in triggering REM sleep or REM sleep atonia is well established (see [117]). Similarly, activation of the cholinergic systems using the acetylcholinesterase inhibitor physostigmine also greatly exacerbates cataplexy in canine narcolepsy, but with various side effects [7]. This cholinergic effect is mediated via muscarinic receptors since muscarinic stimulation aggravates cataplexy, while its blockade suppresses it, and nicotinic stimulation or blockade has no effect [7]. Application of muscarinic antagonists in human narcolepsy is, however, hampered due to its peripheral side effects.

Monoaminergic transmission is also critical for the control of cataplexy. All therapeutic agents currently used to treat cataplexy (i.e., antidepressants or MAOIs) are known to act on these systems. Furthermore, whereas a subset of cholinergic neurons are activated during REM sleep, the firing rate of monoaminergic neurons in the brain stem (such as in the LC and the raphe nucleus) is well known to be dramatically depressed during this sleep stage [118]. In contrast, dopaminergic neurons in the VTA and SN do not significantly change their activity during natural sleep cycles [118]. Using canine narcolepsy, it was recently demonstrated that adrenergic LC activity is also reduced during cataplexy [119].

3.9.5 Preferential Involvement of Adrenergic Neurotransmission in Control of Canine Cataplexy

As mentioned above, tricyclic antidepressants have a complex pharmacological profile that includes monoamine reuptake inhibition, anticholinergic, α_1 -adrenergic antagonistic, and antihistaminergic effects, making it difficult to conclude which of these pharmacological properties is actually involved in their anticataplectic effects.

In order to determine which property was most relevant, we studied the effects of a large number (a total of 17 compounds) of reuptake blockers/release enhancers specific for the adrenergic, serotonergic, or dopaminergic systems. Adrenergic reuptake inhibition was found to be the key property involved in the anticataplectic effect [120]. Serotonergic reuptake blockers were only marginally effective at high doses and the dopaminergic reuptake blockers were completely ineffective. Interestingly, it was later found that these DA reuptake inhibitors had potent alerting effects in canine narcolepsy [7] (see also Section 3.6.1.2).

We also compared the effects of several antidepressants with those of their demethylated metabolites. Many antidepressants (most typically tertiary amine tricyclics) are known to be hepatically first-pass metabolized into their demethylated metabolites that have longer half-lives and higher affinities for adrenergic reuptake sites [121]. During chronic drug administration, these demethylated metabolites accumulate [121] and can thus be involved in the drug's therapeutic action. The effects of five available antidepressants (amitriptyline, imipramine, clomipramine, zimelidine, and fluoxetine) were compared with those of their respective demethylated metabolites (nortriptyline, desipramine, desmethylclomipramine, norzimelidine and norfluoxetine) [113]. In all cases, the demethylated metabolites were found to be more active on cataplexy than were the parent compounds. We also found that the active dose of all anticataplectic compounds tested positively correlated with the *in vitro* potency of each compound to the adrenergic transporter but not with that of the serotonergic transporter [113]. In fact, the anticataplectic effects were negatively correlated with the *in vitro* potency for serotonergic reuptake inhibition, but this may

be biased since potent adrenergic reuptake inhibitors included in the study have a relatively low affinity to serotonergic reuptake sites. Although most of these results were obtained from inbred *hcrtr2*-mutated narcoleptic Dobermans, similar findings (the preferential involvement of adrenergic system) have also been obtained in more diverse cases of sporadic canine narcolepsy in various breeds donated to our colony (see [122]).

The fact that serotonergic reuptake blockers, also known to have inhibitory effects on REM sleep, have less or no effect on cataplexy is surprising. Like adrenergic cells of the LC, serotonergic cells of the raphe nuclei dramatically decrease their activity during REM sleep [117]. This discrepancy could be explained by a preferential effect of serotonergic projections on REM sleep features other than atonia, for example, in the control of eye movements. In this model, adrenergic projections may be more important than serotonergic transmission in the regulation of REM sleep atonia and thus cataplexy [120]. In favor of this hypothesis, a recent experiment has shown that serotonergic activity does not decrease during cataplexy in narcoleptic canines [123].

3.9.6 Receptor Subtypes Involved in Control of Cataplexy

In order to dissect receptor subtypes that significantly modify cataplexy, more than 200 compounds with various pharmacological properties (cholinergic, adrenergic, dopaminergic, serotonergic, prostaglandins, opioids, benzodiazepines, GABAergics, and adenosinergics) have also been studied in the narcoleptic canine model (see [7] for details). Although many compounds (such as M_2 antagonists, α_1 agonists, α_2 antagonists, dopaminergic D_2/D_3 antagonists, 5-HT_{1A} agonists, TRH analogs, prostaglandin E₂, and L-type Ca^{2+} channel blockers) reduce cataplexy, very few compounds significantly aggravate cataplexy (cataplexy-aggravating effects are assumed to be more specific, since cataplexy can be nonspecifically reduced by unpleasant drug sideeffects) [7]. Among the monoaminergic receptors, blockade of the postsynaptic adrenergic α_{1B} receptors [124] and stimulation of presynaptic α_2 autoreceptors [125] were also found to aggravate cataplexy, a result consistent with a primary adrenergic control of cataplexy. We also found that small doses of DA D_2/D_3 agonists significantly aggravated cataplexy and induced significant sleepiness in these animals [126, 127]. The cataplexy-inducing effects of D_2/D_3 agonists are, however, difficult to reconcile considering the fact that dopaminergic reuptake blockers (in contrast to adrenergic reuptake inhibitors) have absolutely no effect on cataplexy [120] (see also Section 3.9.5). We also found recently that sulpiride (a D_2/D_3 antagonist) significantly suppresses cataplexy in the canine model but has no effect on REM sleep [128]. D_2/D_3 agonists are clinically used for the treatment of human periodic leg movements during sleep (PLMS). Incidence of PLMS is high in human narcolepsy, and it also occurs in the narcoleptic Doberman [129]. The dopaminergic system (i.e., D_2/D_3 receptor mechanisms) may thus be specifically involved in sleep-related motor control rather than REM sleep.

The sites of action of D_2/D_3 agonists were also investigated by local drug perfusion experiments, and a series of experiments identified acting sites for these compounds. These include dopaminergic nuclei or cell groups, such as the VTA [127], SN [73], and A11 [130] (a diencephalic DA cell group that directly projects to the spinal ventral horn), suggesting a direct involvement of DA cell groups and DA cell body autoreceptors in the regulation of cataplexy.

The mechanism for emotional triggering for cataplexy remains to be studied, but it is possible that multiple brain sites and multiple functional and anatomical systems are involved.

3.9.7 Monoamine Oxidase Inhibitors

MAOIs are known to potently reduce REM sleep and are therefore candidate anticataplectic agents. This has led several investigators to use MAOIs for the treatment of narcolepsy [131, 132]. The extracellular effect of naturally released catecholamine is terminated by either reuptake or enzymatic degradation, either by MAO and/or catechol-*O*-methyl transferase. MAO is a flavin-containing dominating enzyme located in the outer membranes of neural and glial mitochondria (see [112]). It exists as two forms: MAO_A, blocked by clorgyline and with high affinity for noradrenaline and 5-HT, and MAO_B, insensitive to clorgyline and with high affinity for phenylethylamine and DA (see [112]).

Even if these compounds are clearly active on narcolepsy [131, 132] and may be useful in cases refractory to more conventional treatment, the first-generation MAOIs are rarely used in clinical practice to date due to their poor safety profile (e.g., the cheese effect) (see [132a]). It is also dangerous to use other drugs with sympathomimetic effects (tricyclic antidepressants, amphetamine-like compounds, or simply catecholaminergic cardiac stimulants) in patients treated with MAOIs due to the existence of interactions (sometimes fatal) that are impossible to predict (see [112]). Other side effects include edema, impotence, weight gain, insomnia, long-term hypertension, and psychological disturbances (see [112]). Drug withdrawal may lead to REM sleep rebound with exacerbation of the narcolepsy and the development of vivid nightmares [131]. In addition, the first generation of MAOI (irreversible MAOIs) had the unique property of binding covalently to the active site of the enzyme ("suicide substrate"), thus leading to long-term (up to several weeks) enzymatic inhibition even after a single dose (see [112]).

A safer generation of MAOIs is now becoming available. These include compounds with selective MAO_A or MAO_B inhibition and/or a reversible enzymatic inhibition profile. In contrast to irreversible MAOIs, reversible MAOIs are substrates for the MAOs and compete with the endogenous monoamines (see [112]). Some of these new reversible MAOIs (brofaromine, moclobemide) are now being used in clinical trials in Europe and seem to be effective and safe for the treatment of human narcolepsy without noticeable side effects [133]. These compounds can be used with minimal dietary precautions.

Selegiline is a potent irreversible MAO_B selective inhibitor used in the treatment of Parkinson's disease. This compound is essentially a methamphetamine derivative and is metabolized to a significant extent into amphetamine and methamphetamine (9–30 and 20–60% are found in urine, respectively); the use of low doses of selegiline does not require dietary restriction. Ten milligrams of selegiline daily has no effect on the symptoms of narcolepsy, but 20–30 mg improves alertness and mood and reduces cataplexy somewhat, an effect comparable to amphetamine at the same dose [91]. Indeed, an experiment in canines also suggests that the anticataplectic effects of selegiline are likely to be explained by its active metabolites, *L*-amphetamine and *L*-methylanphetamine [92].

3.9.8 Sodium Oxybate

Sodium oxybate (GHB), taken in the evening and once again during the night reduces cataplectic attacks and other manifestations of REM sleep [134, 135]. Its elimination half-life is 1–2 h, and it increases NREM sleep stages 3 and 4, decreases nighttime awakenings, and consolidates fragmented REM sleep [135, 136]. Recent studies have demonstrated a measurable improvement in patients' reported daytime sleepiness and a moderate reduction in cataplexy. Although improvement in sleepiness occurs relatively quickly, anticataplectic effects appeared one to two weeks after the initiation of the treatment. GHB is reported to possess inhibitory effects through GABA_B receptors, but the precise mechanisms of action of GHB on sleepiness and cataplexy are unknown. GHB given at bedtime and with a second dosage upon awakening during the night (at least 3 h before rising time) may also help consolidate nocturnal sleep. If the patient wakes up during the night, he (or she) may experience dizziness and confused states. One problem with GHB is the nonmedical use of this compound to elicit an altered state of consciousness with important social and legal implications. Its clinical use has recently been approved in the United States by the FDA.

3.10 TREATMENT OF SLEEP PARALYSIS AND HYPNAGOGIC HALLUCINATIONS

The treatment of these two symptoms is much less well codified. Hypnagogic hallucinations can be quite bothersome and often occur in patients who also suffer from frequent nightmares. As they are a manifestation of sleep onset REM sleep, the compounds that suppress REM sleep are usually helpful in alleviating this symptom, and tricyclic antidepressant treatment has been reported to have some beneficial effects [137]. Sleep paralysis only rarely requires treatment, but tricyclic antidepressants are also very effective for preventing this symptom. Recently, high doses (60 mg daily) of fluoxetine have been advocated as a very active treatment for isolated sleep paralysis [138]. GHB is also effective in suppressing both hypnagogic hallucinations and sleep paralysis [135].

3.11 TREATMENT OF DISTURBED NOCTURNAL SLEEP

Insomnia is a major complaint in narcoleptic subjects. Several studies reported that benzodiazepine hypnotics are effective in consolidating nighttime sleep in narcoleptic patients [139]. GHB (a compound with REM- and SWS- inducing properties) has also been used for consolidating nighttime sleep, an effect that leads to decreased EDS and cataplexy the following day [135]. Alternatively, this short half-life sedative hypnotic may induce rebound insomnia-like status the following day and produce alertness during daytime. Due to its positive libido effects, its SWS-enhancing properties, and the reported connection between SWS and growth hormone release, the drug is, unfortunately, widely abused by athletes and other populations [140]. The compound has also been reported to increase periodic leg movements in narcoleptic patients [141].

3.12 FUTURE ANTICATAPLECTICS

Since the occurrence of cataplexy in humans is tightly associated with hypocretin ligand deficiency, hypocretin replacement may be a new attractive treatment choice in human narcolepsy.

The effects of hypocretin-1 (hypocretin-2 has much lower in vivo biological activity, possibly due to its biological instability) administration on sleep and narcolepsy symptoms have been evaluated [97, 142]. Central administration of hypocretin-1, for example in the ventricle of wild-type rodents or normal canines, is strongly wake promoting [97]. This effect is likely to be, at least in part, mediated by the *hcrtr2* receptor, as intracerebroventricular hypocretin-1 at the same dose (10–30 nmol) did not promote wakefulness in *hcrtr2*-mutated narcoleptic canines [97]. A lack of wake-promoting effects of hypocretin-1 was also observed in *hcrtr2* KO mice (Mieda et al., personal communication).

Experiments conducted after intravenous administration of hypocretin-1 have been performed in *hcrtr2*-mutated canines and in two hypocretin-ligand-deficient narcoleptic dogs. In spite of a previous report [142], we were unable to detect any significant effect even at very high doses of hypocretin-1 in *hcrtr2*-mutated animals [97]. This result was not surprising considering the lack of effects after central administration of the same dose in these animals lacking *hcrtr2*. More interestingly, a possible very slight and short lasting suppression of cataplexy was observed in a single hypocretin-deficient narcoleptic animal at extremely high intravenous doses [97, 143]. Intrathecal administration of hypocretin-1 by implanting a Medtronic pump with catheterization of the cisterna magna was also carried out in a single hypocretin-deficient narcoleptic canine [143]. However, no significant effect on cataplexy was observed [143], probably because the hypocretin-1 did not diffuse into upper ventricular compartments. Additional studies using intraventricular rather than intracisternal injections will be needed to verify that hypocretin-deficient narcoleptic canines are responsive to supplementation.

Using hypocretin neuron-ablated narcoleptic mice (orexin/ataxin 3 transgenic mice), Mieda et al. recently demonstrated that replacement of central hypocretin by either pharmacological (intracerebroventricular injection of hypocretin-1) or genetic (ectopic expression of hypocretin in the brain) manipulations allowed for the rescue of the narcolepsy–cataplexy phenotype [98]. These results indicate that hypocretin neuron-ablated mice retain the ability to respond to hypocretin neuropeptides and that hypocretin receptors, intracellular signaling, postsynaptic neural networks, and other downstream neurotransmitter pathways remain anatomically and functionally intact. Most importantly, a temporally regulated and spatially targeted secretion of hypocretin is not likely to be necessary to prevent narcoleptic symptoms [98]. The potential treatment of narcolepsy–cataplexy symptoms in humans by using agonists for hypocretin receptors is a promising new field. Development of small-molecular-weight nonpeptide agonists will be essential for this purpose.

Experiments in canine narcolepsy have suggested that dopamine D₂/D₃ receptor mechanisms may be more specifically involved in regulation of cataplexy (and sleep-related motor control) than in REM sleep, and it is interesting to evaluate anticataplectic effects of D₂/D₃ antagonists in humans.

Several new classes of wake-promoting compounds possibly applied to human narcolepsy were discussed earlier. It is interesting to note that some of these

compounds, such as H_3 antagonists and TRH, also potently reduce cataplexy in the canine model [103, 104]. The modes of action of anticataplectic effects of these compounds are not yet known, and further evaluations of anticataplectic effects of these compounds are warranted.

3.13 CONCLUSIONS

Over 90% of diagnosed narcoleptic patients are reported to take medications to control symptoms [63]. Amphetamine-like stimulants have been used in the treatment of EDS in narcolepsy and various other conditions for decades, yet only recently has the mode of action of these drugs on vigilance been characterized. In almost all cases, the effects on vigilance were found to be mediated via the effects on the DAT. This has generally led to the widely accepted hypothesis that wake-promoting effects will be impossible to differentiate from abuse potential effects for these compounds. Importantly, however, the various medications available have differential effects and potency on the DAT and on monoamine storage/release. It thus appears more likely that complex properties [e.g., the ability to release DA rather than simply block reuptake plus the combined effects on other monoamines (such as 5-HT)] may be important to explain the characteristic of the wake-promoting effect of each compound.

The mode of action of modafinil remains controversial and may involve dopaminergic and/or nondopaminergic effects. Whatever its mode of action, the compound is generally found to be safer and to have a lower abuse potential than amphetamine stimulants. Its favorable side-effect profile has led to an increasing use outside the narcolepsy indication, most recently in the context of shift work disorder and residual sleepiness in treated sleep apnea patients. This recent success exemplifies the need for developing novel and nonamphetamine wake-promoting compounds. A need for treating daytime sleepiness extends well beyond the relatively rare indication of narcolepsy-cataplexy.

Cataplexy is currently treated with antidepressants, a class of compounds that enhance monoaminergic neurotransmission by inhibition of monoamine reuptake (NE, 5-HT, DA). Most narcolepsy-cataplexy patients also take wake-promoting compounds, but these have little effect on cataplexy. Experiments in canine narcolepsy suggest a preferential involvement of NE rather than 5-HT reuptake inhibition in the anticataplectic properties of the drugs. DA reuptake inhibition does not reduce cataplexy but significantly enhances wakefulness. In humans, compounds with NE reuptake inhibition also reduce cataplexy. SSRIs are also very commonly used as anticataplectics in the human. This is mostly due to their better side-effect profiles, but the anticataplectic effects of these compounds are rather modest. Recently, selective NE and NE/5-HT reuptake inhibitors were introduced, and evaluations of these are in progress and may bring profound beneficial effects.

MAOIs are another choice of anticataplectic medication, but use of classical, nonselective, irreversible MAOIs is hampered by various side effects, including hypertensive crisis. Reversible and selective MAOIs are available in some countries, and this may be useful for some severe or refractory cataplexy cases.

Other classes of compounds with possible applications in the development of novel stimulant/anticataplectic medications include the histamine system (especially

H₃ receptor antagonists), TRH system (TRH analogs), adenosinergic system, adrenergic system (e.g., some NE reuptake inhibitors), GABAergic system (e.g., inverse benzodiazepine agonists), and glutamatergic system (ampakines).

Finally, hypocretin replacement therapy may be more straightforward and efficient for the treatment of both cataplexy and sleepiness, but the development of small-molecular-weight peptide agonists is essential. If these are effective in humans, cell transplantation and/or gene therapy may also be developed in the near future.

4.1 LATERAL HYPOTHALAMUS

Observations on humans and experimental animals with localized hypothalamic lesions led to the earliest notions about the role of the lateral hypothalamus (LH).

Studying patients with encephalitis lethargica, von Economo [1] proposed that the posterior hypothalamus (including the LH) was required for maintaining the awake state. Ablations of the monkey LH led to coma and hypophagia, whereas ablations of the medial hypothalamus led to hyperphagia [2–5]. Thus, the LH was known to play a role in both arousal and energy balance, both important aspects of motivated behavior. Additionally, animals lever press for electrical stimulation when electrodes are placed within the LH [6], further implicating it as a reward-mediating structure. The signaling molecules and circuitry responsible for coordinating these behaviors remained unknown until the discoveries of the hypocretin (Hcr) and melanin-concentrating hormone (MCH) systems.

4.2 DISCOVERY OF HYPOCRETINS

An open-system search for undiscovered hypothalamic regulatory peptides provided the first glimpse of the hypocretins. Gautvik and colleagues [7] conducted a systematic subtractive hybridization survey aimed at identifying messenger RNA (mRNA) species whose expression was restricted to discrete nuclei within the rat hypothalamus. Among these was a species whose expression, as detected by *in situ* hybridization analyses (Fig. 4.1), was restricted to a few thousand neurons that were bilaterally distributed within the dorsolateral hypothalamus [7, 8]. The mRNA migrated in northern blots at ~700 nucleotides, detectable during brain development at low concentrations as early as embryonic day 18 and increasing dramatically in concentration after the third postnatal week.

A large collaborative study to identify endogenous ligands for orphan G-protein-coupled receptors (GPCRs) discovered the peptides independently [9]. This group referred to the peptides as orexins because they stimulated acute food intake when

Figure 4.1 First glimpse of hypocretin system. *In situ* hybridization of rat coronal section with complementary DNA (cDNA) isolated in subtractive hybridization study detecting a few thousand neurons in the dorsal–lateral hypothalamus [7].

administered to rats during the daytime. In this chapter, we will refer to the peptides by their first-used name, the hypocretins, but the terms are interchangeable and are both used extensively in the large literature that has grown up around the peptides.

The sequences of the rat [569 non-poly(A) nucleotides] and homologous mouse (582 nucleotides) mRNAs each encodes a 130-residue putative secretory protein with an apparent signal sequence and two additional phylogenically conserved sites for potential proteolytic maturation followed by modification of the carboxy-terminal glycines by peptidylglycine α -amidating monooxygenase [8]. These features suggested that the product of this hypothalamic mRNA served as a preprohormone for two C-terminally amidated, secreted peptides. One of these, hypocretin 2 (Hcrt2, or OxB), was, on the basis of the putative preprohormone amino acid sequence, predicted to contain precisely 28 residues. The other, hypocretin 1 (Hcrt1, or OxA), had a defined predicted amidated C-terminus but, because of uncertainties as to how the amino terminus might be proteolytically processed, an undefined N-terminal extent [8]. The C-terminal 19 residues of these two putative peptides shared 13 amino acid identities, suggesting that the peptides had related structures and functions. This region of Hcrt2 contained a seven-amino-acid match with secretin. Antisera generated against synthetic peptides corresponding to regions of the deduced prohypocretin sequence and to bacterially expressed preprohypocretin have been generated [8, 10–12]. The antisera are specific for the hypocretin-related peptides and have been used extensively to characterize the protein in both anatomical and enzyme-linked immunosorbent assay (ELISA)–type studies, described below.

The detection of the two hypocretin peptides within the brain allowed the exact structures of these endogenous peptides to be determined by mass spectroscopy [9]. The sequence of endogenous Hcrt2, RPGPPGLQGRLQRLQLQANGNHAA GILTM-amide, was the same as that predicted from the cDNA sequence. The N-terminus of Hcrt1 was found to correspond to a genetically encoded glutamine that was derivatized as pyroglutamate. Hcrt1 (33 residues: *EPLPDCCRQKTCSCRL YELLHGAGNHAAAGILTL-amide) contains two intrachain disulfide bonds. Human Hcrt1 is identical to the rodent peptide, whereas human Hcrt2 differs from rodent Hcrt2 at two residues [9].

The mouse hypocretin gene, *HCRT*, is located on chromosome 11, and the human *HCRT* gene maps to chromosome 17q21–q24. Genes that encode conserved preprohypocretins have been detected in pufferfish and frog species, suggesting that the gene arose early in the chordate lineage [13]. Sequence similarities with various members of the incretin family, especially secretin, suggest that the preprohypocretin gene was formed from the secretin gene by three genetic rearrangements: first, a duplication of the secretin gene; second, deletions of the N-terminal portion of the 5' duplicate and the C-terminal portion of the 3' duplicate to yield a secretin with its N- and C-termini leap frogged (circularly permuted); and third, a further duplication of the permuted gene, followed by modifications, to form a secretin derivative that encoded two related hypocretin peptides [13].

Consistent with the hypothesis that the hypocretins and secretin are phylogenically related, portions of their three-dimensional solution structures, as determined by nuclear magnetic resonance, are similar despite their leap-frogged primary sequence, consisting of two adjacent α helices (6–7 and 9–14 amino acids long) separated by a short 2–3-amino-acid turn [14–16]. The longer helix corresponds to the region of identity between the two peptides.

4.3 TWO HYPOCRETIN RECEPTORS

Sakurai and collaborators [9] prepared transfected cell lines stably expressing each of 50 orphan GPCRs and then measured calcium fluxes in these cell lines in response to fractions from tissue extracts. One of these transfected cell lines responded to a substance in a brain extract. Mass spectroscopy showed that this substance was a peptide whose sequence was later identified as that of endogenous Hcrt1. The initial orphan GPCR, Hcrtr1 (also referred to as OX1R), bound Hcrt1 with high affinity but Hcrt2 with 100- to 1000-fold lower affinity. A related GPCR, Hcrtr2 (OX2R), sharing 64% identity with Hcrtr1, was identified by searching database entries with the Hcrtr1 sequence, had a high affinity for both Hcrt2 and Hcrt1 [9]. These two receptors are highly conserved (95%) across species. Radioligand binding studies and calcium flux measurements have shown Hcrt1 to have equal affinity for Hcrtr1 and Hcrtr2, whereas Hcrt2 has ~10-fold greater affinity for Hcrtr2 than for Hcrtr1 [17].

4.3.1 Agonists and Antagonists

Substitution of alanine for leucine at position 11 of human Hcrt2 ([A¹¹]Hcrt2) produces a modified agonist 100-fold more selective than native Hcrt2 for Hcrtr2 over Hcrtr1 [18]. Several Hcrt2 analogs with > 1000-fold selectivity for Hcrtr2 and a truncated form of Hcrt1 (residues 2–23) with modest Hcrtr1 preference have also been produced [19].

SB-334867 [1-(2-methylbenzoxazol-6-yl)-3-[1,5]naphthyridin-4-yl urea] is an antagonist that has an affinity of 40 nM for Hcrtr1 and is more than 50-fold selective over Hcrtr2 and other GPCRs and ion channels [20–22]. SB-408124 [1-(6,8-difluoro-2-methyl-quinolin-4-yl)-3-(4-dimethylamino-phenyl)-urea] is slightly more potent and has greater Hcrtr1 selectivity than SB-334867 [17]. Both compounds are systemically bioavailable and brain penetrant. An Hcrtr1-selective radioligand antagonist has also been described [23]. *N*-Acyl-6,7-dimethoxy-1,2,3,4-tetrahydroisoquinoline was the first Hcrtr2-selective antagonist [24]. More recently a compound [9,1-(2,4-dibromo-phenyl)-3-((4*S*,5*S*)-2,2-dimethyl-4-phenyl-[1,3]dioxan-5-yl)-urea] has been produced that has a 600-fold selectivity for Hcrtr2 over Hcrtr1 [25].

4.4 HYPOCRETIN CELL BODIES

A few thousand neurons highly positive for Hcrt mRNA and immunoreactivity are located between the rat fornix and the mammillothalamic tracts [7, 8, 10, 26, 27]. These are first detected at embryonic day E18 [28]. Beginning at E20, hypocretin antisera detect a prominent network of axons that project from these cells to other neurons in the perifornical and posterior hypothalamus. Both mRNA and peptide expression diminish after one year of age [29]. The human lateral hypothalamus contains 50,000–80,000 hypocretin neurons [30]. With the exception of one report on Hcrt in the enteric nervous system [31], there is no other place in the brain or periphery where Hcrt-producing neuronal perikarya have been found. Hcrt neurons are 20–30 μm in diameter and are multipolar or fusiform in shape, with two to four primary dendrites bearing few spines. In addition to rats, mice, and humans, Hcrt

neurons with a similar restricted hypothalamic distribution have been detected in monkey, hamster, cat, sheep, pig, chicken, various amphibians, and zebrafish.

The LH contains a collection of neurons that express MCH, a peptide that has been implicated in feeding-related behavior [32]. MCH and hypocretin neurons are distinct but spatially intermingled, each set with a different topological distribution [10, 26, 27, 33]. Neither population is cholinergic, but both populations express acetylcholinesterase [34]. There is a nearly one-to-one correspondence between LH neurons that express the opioid receptor agonist dynorphin and the hypocretin neurons [35], and nearly all Hcrt neurons express secretogranin II [36]. Glutamate, the excitatory amino acid transporter EAAT3, and the vesicular glutamate transporters VGLUT1 and VGLUT2 are expressed by Hcrt neurons [37–41]; thus, Hcrt neurons are likely to be glutamatergic. Other proteins detected in Hcrt neurons include the γ -aminobutyric acid (GABA) type A receptor ϵ subunit, serotonin 5-HT_{1A} receptor, μ -opioid receptor, pancreatic polypeptide Y4 receptor, adenosine A1 receptor, leptin receptor, precursor protein convertase, signal transduction and activator of transcription 3 (STAT-3), and the neuronal activity-regulated pentraxin (NARP), implicated in clustering of ionotropic glutamate receptors [33, 42–49].

4.4.1 Hcrt Projections

Projections from Hcrt-immunoreactive cell bodies are detected throughout the brain, with the highest density of terminal fields seen in the hypothalamus [8, 10, 27]. Hypothalamic regions receiving projections include the LH and posterior hypothalamic areas (regions of Hcrt and MCH neuronal populations), the dorsomedial hypothalamus (DMH), the paraventricular hypothalamic nucleus, and arcuate nucleus. Hcrt is reciprocally connected with neuropeptide Y (NPY) and leptin receptor–positive neurons in the arcuate nucleus [50], an area important in feeding behaviors and endocrine regulation. Hcrt neurons also make reciprocal synaptic contact with neighboring MCH neurons [51, 52].

Prominent Hcrt fibers project from the LH to apparent terminal fields in many areas of the brain. Peyron and colleagues [10] referred to four Hcrt efferent pathways: dorsal and ventral ascending pathways and dorsal and ventral descending pathways. The dorsal ascending pathway projects through the zona incerta to the paraventricular nucleus of the thalamus, central medial nucleus of the thalamus, lateral habenula, substantia innominata, bed nucleus of the stria terminalis, septal nuclei, dorsal anterior nucleus of the olfactory bulb, and cerebral cortex. The ventral ascending pathway projects to the ventral pallidum, vertical and horizontal limb of the diagonal band of Broca, medial part of the accumbens nucleus, and olfactory bulb. The dorsal descending pathway projects through the mesencephalic central gray to the superior and inferior colliculi and the pontine central gray, locus coeruleus (LC), dorsal raphe nucleus, and laterodorsal tegmental nucleus. A second bundle of fibers projects through the dorsal tegmental area to the pedunculopontine nucleus, parabrachial nucleus, subcoeruleus area, nucleus of the solitary tract, parvocellular reticular area, dorsal medullary region, and caudal spinal trigeminal nucleus. This tract continues to all levels of the spinal cord [11]. The ventral descending pathway runs through the interpeduncular nucleus, ventral tegmental area (VTA), substantia nigra pars compacta, raphe nuclei and reticular formation, gigantocellular reticular nuclei, ventral medullary area, raphe magnus, lateral

paragigantocellular nucleus, and ventral subcoeruleus. The cumulative set of projections is consistent with the combined patterns of expression of the two hypocretin GPCRs (discussed below). Although a large proportion of Hcrt neurons contribute projections to multiple terminal fields, various subgroups of cells make preferential contributions to particular fields [53, 54]. The projection fields in humans are comparable to those in rodents [30]. The diffuse nature of Hcrt projections provided the first evidence of the potential for multiple physiological roles for the peptides.

4.4.2 Hcrt at Synapses

Electron microscopic examination revealed that hypocretin immunoreactivity is associated with the rough endoplasmic reticulum, the Golgi network, and cytoplasmic dense-core vesicles [8, 10, 50]. The latter have been observed along myelinated axons and at presynaptic boutons apposed to dendritic shafts in both the periaqueductal gray and the LC, where the synapses are with tyrosine hydroxylase-positive noradrenergic dendrites. The accumulation of the hypocretins within dense-core vesicles at axon terminals suggested that they might have intercellular signaling activity. In the brain stem and spinal cord of cats, age-dependent enlargement of hypocretin synapses has been observed, suggesting age-related changes in Hcrt transmission [55].

4.4.3 Hcrt Afferents

In addition to reciprocal connections with the MCH neurons of the LH and with NPY/agouti-related peptide neurons and galaninlike peptide neurons [56] of the arcuate, corticotropin-releasing factor (CRF)-positive inputs arising from the paraventricular hypothalamic nucleus have been detected in close apposition to Hcrt perikarya [54]. Hypocretin neurons receive direct projections positive for arginine-vasopressin and vasoactive intestinal peptide from neurons in the suprachiasmatic nucleus (SCN) [37], which is responsible for generating the circadian rhythm, and also innervation from the DMH, which itself responds to SCN input [57].

Hcrt neurons are predominantly controlled by local glutamatergic excitatory interneurons [39]. Perikaryal GABA input onto the Hcrt neurons is very minimal, approximately 10% that of the glutamatergic input. Other afferents include brain stem noradrenergic and dorsal raphe nucleus serotonergic inputs as well as cholinergic afferents [39, 58].

4.4.4 Receptor Distributions

The mRNAs that encode the two hypocretin receptors and the receptor proteins themselves, detected by immunohistochemistry, are both enriched in the brain and moderately abundant in the hypothalamus but have different distributions within the brain [59–61]. Hcrt1 mRNA is prominent in the prefrontal and intralimbic cortex, hippocampus, paraventricular thalamic nucleus, ventromedial hypothalamic nucleus, dorsal raphe nucleus, LC, laterodorsal and pedunculopontine tegmental nuclei (at higher density than Hcrt2), pontine raphe, raphe magnus, raphe obscurus, dorsal motor vagal complex, and spinal cord. Additional forebrain regions expressing moderate to high levels of Hcrt1 mRNA are the tenia tecta, bed nucleus of the stria

terminalis, horizontal limb of the diagonal band of Broca, and medial amygdala. Immunoreactive terminals have been detected in the LH. This receptor has also been detected in the retina [62].

Hcrtr2 mRNA (there are two alternative splice forms, each encoding proteins with slightly different structure and anatomical distribution but no demonstrated functional differences) [63] is detected in the cerebral cortex, septal nuclei, hippocampus, medial thalamic groups, raphe nuclei, and various nuclei of the hypothalamus, including the tuberomammillary nucleus, dorsomedial nucleus, paraventricular nucleus, ventral premammillary nucleus, ventral periaqueductal gray, midbrain reticular formation, dorsal interpeduncular nucleus, Barrington's nucleus, sensory trigeminal nucleus, ventrolateral medulla, and dorsal vagal nucleus. Hcrtr2 mRNA is prominent in the medial septum, vertical and horizontal limbs of the diagonal band of Broca, substantia innominata, and cortical amygdala.

Both receptors are detected in dorsal raphe, the VTA, paraventricular thalamic nucleus, and intergeniculate leaflet, with lesser density in the rhomboid, reunions, and other midline nuclei. In the cerebral cortex, Hcrtr1 mRNA is expressed primarily in layers II, III and V, whereas Hcrtr2 mRNA is found at higher density in layers II and VI and more diffusely in other layers. In the hippocampus, Hcrtr1 is expressed mainly in the CA2 region and medial dentate gyrus, while Hcrtr2 was most abundant in CA3 [64].

The distribution of Hcrtr receptors is largely consistent with Hcrtr axon innervation patterns. The composite distribution of the two Hcrtr receptors strongly resembles the distribution of the MCH receptor [65]. In the LC, amygdala, and other brain stem noradrenergic groups, MCH receptor mRNA distribution is similar to that of the Hcrtr1. In regions such as the septum, hypothalamus, and much of the brain stem, the distribution of MCH receptor mRNA resembles that of the Hcrtr2 [65].

The Hcrtr receptors are not restricted to the central nervous system (CNS): In the periphery, they are widely expressed, especially in endocrine tissues. Hcrtr1 or Hcrtr2 have been detected in the pituitary, adrenal gland, testis, gastrointestinal tract, pancreas, and pineal gland.

4.5 HYPOCRETINS: EXCITATORY NEUROTRANSMITTERS

Three observations suggested that the hypocretins might possess neurotransmitter activities: (i) the detection of Hcrtr neurons in a specialized region of the hypothalamus, (ii) the processing of the precursor into two related peptides, and (iii) the detection of the peptides in vesicles at synapses. Bath application of synthetic Hcrtr2 to mature hypothalamic neurons evoked increases in the frequency of postsynaptic currents [8]. Hypocretin-mediated excitation has been found in a large number of brain regions, many of them involved in arousal. Hypocretin increases activity in the hypothalamus [66, 67], LC [49, 68, 69], dorsal raphe [70, 71], dorsal horn of the spinal cord [72], spinal motoneurons [73], nucleus of the solitary tract [74], dorsal motor nucleus [75], dorsolateral tegmentum [76], tuberomammillary nucleus [77, 78], basal forebrain [79, 80], neocortex [81], hippocampus [82], midline thalamus [83], and trigeminal nucleus [84].

Hcrtr2 has a potent effect at both presynaptic and postsynaptic receptors [66]: In the presence of tetrodotoxin, the hypocretins increase the frequency, but not the

amplitude, of miniature postsynaptic currents (presynaptic effect) and evoke an increase in cytoplasmic calcium by opening plasma membrane Ca^{2+} channels in arcuate postsynaptic neurons (postsynaptic effect). Most synaptic activity in hypothalamic circuits is attributable to axonal release of GABA or glutamate. Hypocretin, acting directly at axon terminals, can increase the release of each of these amino acid transmitters, as demonstrated by whole-cell patch-clamp recording [66].

Both Hcrt1 and Hcrt2 evoke rises in Ca^{2+} , as measured by fura-2 imaging, in about one-third of hypothalamic neurons, probably by opening a transient receptor potential channel (TRPC)-type calcium channel [85–87]. Responses to hypocretin are completely blocked by the protein kinase C-specific inhibitor bisindolylmaleide and by phospholipase C (PLC) inhibitors [66], suggesting that the hypocretins work through a family of guanosine triphosphate (GTP) binding proteins (G_q) that activate protein kinase C (PKC) and mobilization of intracellular calcium. G_q -activated signaling cascades result in phosphorylation of Ca^{2+} channels, which can increase Ca^{2+} conductance and neuronal excitability [88, 89]. The nonamidated forms of the peptides are not electrophysiologically active [88]. In the substantia nigra pars reticulata, hypocretin stimulation was sensitive to an inhibitor of protein kinase A, which mediates effects of cyclic adenosine monophosphate (cAMP), but insensitive to blockers of PKC [90], implicating a role of the G_s system.

The adrenal glands also express Hcrt2 [91, 92]. Treatment of human adrenal membranes from fetal or adult tissue with Hcrt1 increased the labeling of G_s and G_i in both preparations and additionally G_q in the adult preparation. Thus, although the majority of hypocretin signaling is excitatory, it may be inhibitory in some cases [93]. Acting as excitatory peptides, the hypocretins can enhance the activities of both excitatory and inhibitory neurons.

4.6 FEEDING AND METABOLISM

Sakurai and colleagues [9] found that intracerebroventricular (ICV) administration of either Hcrt1 or Hcrt2 increased short-term food consumption in rats. Furthermore, rats that had been deprived of food for 48 h showed increased concentrations of hypocretin mRNA and peptides in the hypothalamus [9, 94]. Feeding responses can be elicited by local administration of Hcrt1 to the paraventricular nucleus, the dorsomedial nucleus, the lateral hypothalamus, or the perifornical area [95]. ICV administration of Hcrt2 also increases food intake in sheep [96] and goldfish [97].

Many observations leave little doubt that the hypocretin system influences and is influenced by primary nutritional homeostasis circuits, but other findings suggest that the hypocretins are not critical players in feeding activities but rather play roles in increasing arousal and motivation levels so that feeding can take place. Hypocretin-immunoreactive fibers form synapses on neurons in the arcuate nucleus that contain NPY, an important orexigenic (appetite-stimulating) peptide, and with pro-opiomelanocortin (POMC)-expressing neurons, which produce α -melanocyte-stimulating hormone, a satiety factor [26, 27, 50]. Hypocretin neurons express leptin receptors [33, 50, 98], and preprohypocretin mRNA expression is reduced in *obese* (*ob/ob*) mice [99], which lack leptin. Hypocretin neurons receive inputs from NPY- and agouti-related peptide (AgRP)-positive neurons in the arcuate nucleus, which themselves express leptin receptors, and NPY stimulates *c-fos* expression by

hypocretin neurons, whereas NPY receptor antagonists block the feeding effect of hypocretins [100, 101]. Administration of an antiserum directed against Hcrt1 attenuates the feeding response to ICV NPY, and pharmacological blockade of the NPY receptor reduces the feeding stimulatory effect elicited by Hcrt1 [100–102]. Hcrt-expressing cells respond to circulating leptin by reducing Hcrt1 concentrations and *c-fos* expression [102–104]. Also supporting the idea that the hypocretin neurons are involved in feeding is the observation that they express STAT3, a transcription factor that is induced by leptin [33]. However, whereas NPY-induced feeding is completely inhibited by leptin, the Hcrt feeding response is only partially suppressed by leptin [105]. Cultured neurons isolated from the arcuate nucleus show either of two responses to the Hcrts [106]. In neurons immunoreactive for NPY, intracellular Ca^{2+} is increased in response to Hcrt1 (more so than Hcrt2), and the increase is blocked by PLC, PKC, and calcium uptake inhibitors, indicative of signaling through Hcrt1 via PLC, PKC, and inositol-1,4,5-triphosphate (IP_3) pathways. In POMC-immunoreactive neurons, the two peptides equipotently decreased Ca^{2+} by a pertussis toxin-sensitive mechanism, indicative of signaling through Hcrt2 via G_i/G_o pathways. The peptides also decreased Ca^{2+} in glucose-responsive neurons in the ventromedial hypothalamus. These three effects are reciprocal to those induced by leptin [106].

Hcrt cells are sensitive to glucose and food deprivation: The activity of hypocretin neurons and their expression of hypocretin mRNA and *c-fos* increase during hypoglycemia and after injection of Intralipid; hypocretin mRNA decreases during glucopenia; and *c-fos* expression increases during fasting [107–112]. Acute administration of the Hcrt1-selective antagonist SB-334867 suppresses food intake in rats. Interestingly, SB-334867 also reduced weight gain for 3–5 days posttreatment [113–115], despite being no longer detectable after 12 h, and repeated administration of the antagonist reduced the food intake and weight gain over 14 days in *ob/ob* mice [116]. These results are consistent with a complex circuitry of appetite-controlling signaling molecules in the arcuate and lateral hypothalamus in which hypocretin might play a role.

Not all data support this notion, though, particularly when the other activities of the hypocretins are considered (see below). Hcrt1-induced increases in food intake were small relative to those induced by NPY infusion [117, 118]. Others have measured no alteration in Hcrt1 peptide concentration or Hcrt mRNA in the rat hypothalamus in response to either fasting or a high-fat diet, and no effect on Hcrt mRNA of experimentally induced diabetes [119–121]. However, Hcrt mRNA increases after leptin administration to fasted mice and increases in response to a high-fat diet [122]. Hcrt1 stimulated acute food consumption in 4-month-old rats but not 25-month-old rats [123] and substantially decreased food intake 2 h after central administration to rhesus monkeys, consistent with an anorectic action [124].

It is difficult to attribute physiological effects to ICV administration of high doses of hypocretin, which might activate circuits other than those that would be activated by local axonal release of the transmitter [66]. And, the Hcrts might be orexigenic only under some physiological states (perhaps related to circadian rhythms or stress). In this regard, it might be significant that the hypocretins activate dopamine-mediated stereotypic behaviors. Hcrt1 peptide concentrations in the hypothalamus are under circadian control and are highest during the awake, dark period in nocturnal rodents [125]. During fasting, Hcrt1 accumulation in the cerebrospinal

fluid (CSF) does not exceed concentrations normal for the waking period, suggesting that some of the food uptake effect may result from arousal rather than direct feeding pressure [126]. Continuous administration of Hcrt1 for seven days in rats does not significantly alter daily food intake, body weight, blood glucose, total cholesterol, or free fatty acid levels [127], suggesting that many of hypocretin's effects may be limited to short-term, immediate stimulation of feeding behavior due to increased wakefulness. That is, animals eat more and are motivated to eat when they are awake. Consistent with these views, although most circadian parameters and behaviors are unaffected in mice in which the Hcrt neurons have been ablated (mice discussed below), increases in wakefulness and locomotor activities that normally precede an anticipated meal during a restricted feeding regimen are greatly diminished in the ablated mice [128–130].

4.7 AUTONOMIC AND ENDOCRINE EFFECTS

Hypocretin neurons receive inputs from brain stem areas that are associated with cardiovascular function and project to the ventrolateral medulla, the LC, the lateral paraventricular nucleus, the nucleus of the solitary tract, the pre-Bötzinger region of the ventrolateral medulla, phrenic motoneurons, and other areas that have been implicated in the regulation of blood pressure, heart rate, and breathing [131, 132]. Projections to the arcuate nucleus also suggested a role in the regulation of hormone release. In the ovine hypothalamus, there are hypocretin terminals on the neurons that produce gonadotropin-releasing hormone, suggesting that hypocretin might particularly modulate reproductive endocrinology [133]. In addition, projections to the raphe magnus and subcoeruleus suggested a role for hypocretins in the regulation of body temperature. The dense hypocretinergic projections to the ventrolateral preoptic area, tuberomammillary nucleus (TMN), pontine reticular formation, pedunculopontine (PPT) and laterodorsal tegmental (LDT) area, and LC suggested involvement in states of arousal [10, 68, 134]. Very strong hypocretin-immunoreactive projections have been described in regions of the spinal cord that are related to modulation of pain [11], and hypocretin-like immunoreactivity has also been detected in the intestinal epithelium [31].

In accordance with the wide distribution of hypocretin terminals, ICV administration of the hypocretins affects not only feeding but also several other functions. Both Hcrt1 and Hcrt2 elevate mean arterial blood pressure, heart rate (both suppressed by SB334867), and oxygen consumption [135–138]. Microperfusion of the Hcrts in pre-Bötzinger or phrenic motoneuron sites increases diaphragm muscle activity [132]. Hcrt1 increases body temperature independent of peripheral thermogenesis, at least in part via clozapine-sensitive pathways in the cerebral cortex [139–142]. Hcrt1 also increases water consumption and stimulates gastric acid secretion in the gut [143, 144] and increases locomotor activity and wakefulness while decreasing slow-wave and depressing rapid-eye-movement (REM) sleep [68, 69, 145–147].

The peptides also stimulate the secretion of luteinizing hormone in ovariectomized and proestrus female rats (suppressed by central administration of SB334867) and hypothalamic explants of male pituitaries [148, 149]. Consistent with these findings, in humans, LH concentration in serum and pulsatile LH secretion are lower in male narcolepsy patients (who lack hypocretin function; see below) than in unaffected

controls [150]. *Hcrtr* concentrations are elevated during proestrus in cycling female rats but not noncycling middle-aged rats and in pregnant rats, and *c-fos* is increased in *Hcrtr* neurons in lactating mice [151–153]. In male rats, *Hcrtr1* increased basal testosterone secretion [154]. *Hcrtr1* decreases the concentrations of circulating growth hormone and prolactin while increasing corticosterone, adrenocorticotrophic hormone (ACTH), and insulin levels [68, 155–159]. Hypoglycemia-induced elevation of pancreatic nerve firing is antagonized by SB334867 microinjection in the dorsal motor nucleus of the vagus, indicative of a central circuit in this pathway [160]. *Hcrtr2*, but not *Hcrtr1*, increases circulating thyroid-stimulating hormone [161] and has direct effects on the pituitary, adrenal, and pineal glands [91, 162, 163].

Both peptides depolarize CRF neurons in the paraventricular hypothalamic nucleus (PVN) and increase CRF, *c-fos*, and arginine vasopressin mRNA concentrations in the PVN and thus have clear effects on the hypothalamic–pituitary–adrenal (HPA) axis and stress-related physiology; various stress paradigms increase *c-fos* expression by *Hcrtr* neurons [67, 164–168]. *Hcrtr2* is directly excitatory on superficial dorsal horn neurons of the spinal cord [71] and exhibits an analgesic effect in models of pain [169]. There are several examples in which either *Hcrtr1* or *Hcrtr2*, but not both peptides, effects a response, suggesting that the two peptides are not redundant. In some cases, the effects can be explained by differential involvement of *Hcrtr1* or *Hcrtr2*; in others, differential resistance of the peptides to degradation may provide the explanation.

4.8 MOTIVATION AND ADDICTION

Hcrtr neurons are highly responsive to morphine and are activated by naltrexone-precipitated withdrawal. However, the response of these neurons is heterogeneous, suggesting that there might be different populations of *Hcrtr* cells [170]. The expression of the *Hcrtr* gene increases only after precipitated withdrawal. The neurons express the μ -opioid receptor; hence their response may be due to direct actions of morphine and naltrexone [44]. These observations might explain why animals self-administer heroin to the LH [171]. *Hcrtr* knockout mice exhibit dramatically attenuated morphine withdrawal symptoms [44]. *Hcrtr* neurons have extensive projections to the mesolimbic dopamine and noradrenergic (LC) pathways, regions well studied for their roles in drug addiction. These neurons also project to and inhibit nucleus accumbens neurons [93].

Rats can be trained to turn a wheel to deliver electrical current to the LH: LH self-stimulation (LHSS). LHSS thresholds measure brain reward systems; lower thresholds represent increased reward. Most drugs of abuse lower LHSS thresholds. LHSS is thought to be rewarding in part because it activates cholinergic neurons in the LDT and the PPT nuclei that consequently activate dopaminergic neurons in the VTA [172]. Hypocretins excite LDT cholinergic neurons both directly and indirectly acting synergistically with glutamatergic afferents [76] to drive dopamine release in the nucleus accumbens by exciting dopaminergic neurons in the VTA. Thus, the *Hcrtr* system acts as a modulator of brain reward function. Interestingly in this regard, naltrexone injected into the accumbens suppresses the *Hcrtr1*-induced acute feeding response, suggesting that the response is mediated by opiodergic pathways involved in motivation [173].

4.9 PAIN AND ANAESTHESIA

In models of pain elicited by noxious stimuli or chronic constriction, Hcrt administered intrathecally or microinjected into the posterior hypothalamus decreased pain parameters [174, 175]. Hypocretin knockout mice (see below) exhibited greater hyperalgesia and less stress-induced analgesia than wild-type mice [176]. Hcrt1 decreases barbiturate anaesthesia time in rats by 15–40%, an action reversed by SB-334867 [177]. *In vitro*, barbiturates inhibit Hcrt-induced norepinephrine release, although they do not interact directly with Hcrt receptors. In isoflurane-anesthetized animals, Hcrt1 elicits arousal without cardiovascular activation, in contrast to its effect on awake animals [178]. Pain and stress activate Hcrt neurons, which respond by inhibiting pain pathways.

4.10 HIPPOCAMPAL PLASTICITY

In vivo studies have shown that Hcrt enhances long-term potentiation in the dentate gyrus induced by high-frequency stimulation in the perforant path [179]. Paradoxically, ICV administration of hcr1 in rats impairs spatial learning in the Morris water maze [180].

In vitro recordings have demonstrated that Hcrt1 can induce long-term potentiation (LTP) at Schaffer collateral CA1 but not mossy fiber CA3 synapses [82]. Pharmacological analysis revealed that Hcrt-induced LTP requires coactivation of ionotropic and metabotropic glutamatergic, GABAergic, as well as noradrenergic and cholinergic receptors. Hcrt may also affect hippocampal physiology indirectly by increasing release of norepinephrine [181]. These data suggest that Hcrt may be involved in regulating the threshold and weight of synaptic connectivity, providing a mechanism for integration of multiple transmitter systems [82]. Thus, the Hcrt also participate in some aspects of metaplasticity.

4.11 NARCOLEPSY: DISEASE OF HYPOCRETIN SYSTEM

Sleep is characterized by complex patterns of neuronal activity in thalamocortical systems [182–184]. The fast, low-amplitude electroencephalogram (EEG) activity of the aroused state is replaced by synchronized high-amplitude waves that characterize slow-wave sleep. This pattern develops further into high-frequency waves that define paradoxical, or REM, sleep. Switching among these states is controlled in part by the activities of neurons in the hypothalamic ventrolateral preoptic nucleus and a series of areas referred to as the ascending reticular activating system, which is distributed among the PPT and LDT, LC, dorsal raphe nucleus (DRN) and TMN and regulates cortical activity and arousal [185]. The balance struck among the various phases of sleep and the rapid transitions from one phase to the next are determined by requirements for wakeful activities, homeostatic pressures for sleep, and circadian influences [186, 187].

The first case of human narcolepsy was reported in 1877 by Westphal, and the sleep disorder acquired its name from Gélinau in 1880. Narcolepsy affects around 1 in 2000 adults, appears between the ages of 15 and 30 years, and shows four

characteristic symptoms: (i) excessive daytime sleepiness with irresistible sleep attacks during the day; (ii) cataplexy (brief episodes of muscle weakness or paralysis precipitated by strong emotions such as laughter or surprise); (iii) sleep paralysis, a symptom considered to be an abnormal episode of REM sleep atonia, in which the patient is suddenly unable to move for a few minutes, most often upon falling asleep or waking up; and (iv) hypnagogic hallucinations, or dreamlike images that occur at sleep onset. These latter symptoms have been proposed as pathological equivalents of REM sleep. The disorder is considered to represent a disturbed distribution of sleep states rather than an excessive amount of sleep.

Studies with monozygotic twins have shown that narcolepsy is weakly penetrant: In only 25% of cases does the monozygotic twin of an affected individual also develop the disorder. Sporadic narcolepsy (which accounts for 95% of human cases) is highly correlated with particular class II human leukocyte antigen (HLA) DR and DQ histocompatibility haplotypes in about 90% of patients, but most people with these haplotypes are not narcoleptic [188]. Because many autoimmune disorders are HLA linked and because of the late and variable age of disease onset, narcolepsy has long been considered a likely autoimmune disorder, but the targets of the immune attack were not known.

Both sporadic and heritable narcolepsy are observed in dogs, and the symptoms resemble those exhibited by human narcoleptics. The first link between the hypocretins and narcolepsy came from genetic linkage studies in a colony of Doberman pinschers in which narcolepsy was inherited as an autosomal recessive, fully penetrant phenotype. Fine mapping and cloning of the defective canine narcolepsy gene showed it to be the gene that encodes the hypocretin receptor *Hcrtr2* [189]. The mutation in the Doberman lineage is an insertion of a short interspersed repeat (SINE element) into the third intron of *HCRT2* that causes aberrant splicing of the *Hcrtr2* mRNA (exon 4 is skipped) and results in a truncated receptor protein. In cells that have been transfected with the mutant gene, the truncated *Hcrtr2* protein does not properly localize to the membrane and, therefore, does not bind its ligands [190]. Analysis of a colony of narcoleptic Labradors revealed that their *HCRT2* gene contained a distinct mutation that resulted in the skipping of exon 6, also leading to a truncated receptor protein. A third family of narcoleptic Dachshunds carries a point mutation in *HCRT2* that results in a receptor protein that reaches the membrane but cannot bind the hypocretins. Genetically narcoleptic dogs have increased CSF levels of Hcrtr, which diminishes until symptoms appear at four weeks, then increases [191]. Administration of immunoglobulins or immunosuppressive/anti-inflammatory drugs doubles time to symptom onset and severity of symptoms, suggesting that *HCRT2* deficits alone are not sufficient to elicit all of the symptomatology initiated by the loss-of-function mutations [192, 193].

In knockout mice in which the hypocretin gene was inactivated by homologous recombination in embryonic stem cells, continuous recording of behavior revealed periods of ataxia which were especially frequent during the dark period [194]. EEG recordings showed that these episodes were not related to epilepsy and that the mice suffered from cataplectic attacks, a hallmark of narcolepsy. In addition, the mutant mice exhibited increased REM sleep during the dark period as did their wild-type littermates, and their EEGs showed episodes of direct transition from wakefulness to REM sleep, another event that is unique to narcolepsy. Waking and non-REM sleep bouts were brief, with more transitions among all three states, suggestive of a

behavioral state instability with low state transition thresholds [195]. Mice with an inactivated *HCRT* gene have a milder narcoleptic phenotype than the *HCRT* knockouts; *HCRT1* knockouts exhibit only a sleep fragmentation phenotype, whereas double *HCRT1* and *HCRT2* mutants recapitulate the full *HCRT* knockout phenotype [196], suggesting that signaling through both receptors contributes to normal arousal, although the role of *HCRT2* is greater than that of *HCRT1*. Similar observations were made in rats in which the hypocretin neurons of the lateral hypothalamus were inactivated by saporin targeting [197], although in this model cataplexy was not observed. However, in mice [198], or rats in which the hypocretin neurons are ablated due to the expression of the toxic ataxin-3 fragment from the *Hcr* promoter, *Hcr* neurons are lost at 17 weeks, and the hallmarks of narcolepsy ensue, including episodes of muscle atonia and loss of posture resembling cataplexy [199].

Nishino and colleagues [200] studied hypocretin concentrations in the CSF of normal controls and patients with narcolepsy by radioimmunoassay. In control CSF, hypocretin concentrations were highly clustered, suggesting that tight regulation of the substance is important. However, of nine patients with narcolepsy, only one had a hypocretin concentration within the normal range. One patient had a greatly elevated concentration, while seven patients had no detectable circulating hypocretin. In an expanded study, hypocretin was undetectable in 37 of 42 narcoleptics and in a few cases of Guillain–Barré syndrome [201]. CSF hypocretin was in the normal range for most neurological diseases but was low, although detectable, in some cases of CNS infections, brain trauma, and brain tumors. Low CSF hypocretin concentrations have also been measured in a patient with acute disseminated encephalomyelitis presenting similarities to von Economo’s encephalitis lethargica which returned to the normal range as daytime sleepiness was reduced [202] and in two patients with Prader–Willi syndrome accompanied by excessive daytime sleepiness (EDS) [203].

Peyron, Thannikal, and collaborators [204, 205] found that, in the brains of narcolepsy patients, they could detect few or no hypocretin-producing neurons. Whether the hypocretin neurons are selectively depleted, as is most likely, or only no longer expressing hypocretin is not yet known, although one report showed some indications of gliosis [205]. The codistributed MCH neurons were unaffected. Furthermore, a single patient with a non-HLA-linked narcolepsy carries a mutation within the hypocretin gene itself. The mutation results in a dominant-negative amino acid substitution in the secretion signal sequence that sequesters both the mutant and heterozygous wild-type hypocretin nonproductively to the smooth endoplasmic reticulum [204]. Amino acid substitutions in *Hcrtr2* have been found in two EDS patients and one Tourette’s syndrome patient: In each case the variant receptor exhibited reduced response to high concentrations of *Hcr* [206].

These findings leave no doubt as to the central role of the hypocretin system in this sleep disorder. Because most cases are sporadic, mutations in the hypocretin gene or those for its receptors can account for no more than a small subset of the human narcolepsies. The HLA association, loss of neurons with signs of gliosis, and age of disease onset are consistent with autoimmune destruction of the hypocretin neurons accounting for the majority of narcolepsy [207], although a non-immune-mediated degenerative process has not been ruled out. For example, studies of hypothalamic slice cultures have revealed that *Hcr* neurons are more sensitive to excitotoxic injury elicited by quinolinic acid than are neighboring MCH neurons, suggesting that

glutamatergic signaling could contribute to their selective loss [208]. Interestingly, hypocretin cell loss has recently been described in Huntington disease (HD) patients [209] and in R6/2 mice, which expresses *exon 1* of the human mutant *HD* gene with ~150 CAG repeats [210]. In advanced stages, these mice display several clinical features reminiscent of HD but relatively little cell death. Thus, Hcrt neurons may have a very low threshold for neuronal apoptosis caused by a variety of environmental stimuli. The narcolepsies as a group are probably a collection of disorders that are caused by defects in the production or secretion of the hypocretins or in their signaling, and these could have numerous genetic, traumatic, viral, and/or autoimmune causes.

Measurement of Hcrt1 in human CSF provides a reliable diagnostic for sporadic narcolepsy. Although local release of Hcrt at its targets within the brain varies during the 24-h day, CSF Hcrt1 levels are relatively stable [125, 211]. In a study of 274 patients with various sleep disorders (171 with narcolepsy) and 296 controls, a cutoff value of 110 pg/mL (30% of the mean control values) was the most predictive of narcolepsy [212]. Most narcolepsy patients had undetectable levels, while a few had detectable but very reduced levels. The assay was 99% specific for narcolepsy.

Hcrt1 has also been detected in plasma, although its origin remains to be demonstrated and high nonspecific background immunoreactivities partially mask its detection. Decreased levels of plasma Hcrt1 were measured in narcoleptic patients using high-performance liquid chromatography separation to confirm that the signal included genuine Hcrt1 [213]. Reductions in daytime plasma Hcrt have been detected in patients with obstructive sleep apneahypopnea syndrome [214, 215].

Given that most human narcolepsy is sporadic and results from depletion of Hcrt-producing neurons, replacement therapies can be envisioned. Small-molecule agonists of the hypocretin receptors might have therapeutic potential for human sleep disorders and might be preferable to the traditionally prescribed amphetamines. ICV administration of Hcrt1 to normal mice and dogs strongly promotes wakefulness [216, 217]. The effect is predominantly mediated by Hcrt2, because the same dose of Hcrt1 has no effect in Hcrt2-mutated narcoleptic dogs [216, 217]. Transgenic expression of preprohypocretin in the brains of mice in which the Hcrt neurons were ablated prevented cataplexy and REM abnormalities, and central administration of Hcrt1 to Hcrt neuron-ablated mice prevented cataplexy and increased wakefulness for 3 h [218]. Hcrt1 has low penetrance of the blood–brain barrier, so a centrally penetrable agonist will need to be devised.

4.12 HYPOCRETIN AND AROUSAL CIRCUITY

Because narcolepsy is the consequence of a defective hypocretin system, it follows that the dominant role of the system is in maintenance of the waking state and suppression of REM entry, and data about the hypocretins give insights as to how this is accomplished (Fig. 4.2). The hypocretin neurons project to various brain stem structures of the ascending reticular activating system which express one or both of the hypocretin receptors and have been implicated in regulating arousal. The noradrenergic neurons of the LC, the serotonergic neurons of the dorsal raphe, and the histaminergic neurons of the TMN are all so-called REM-off cells: Each group fires rapidly during wakefulness, slowly during slow-wave sleep, and hardly at

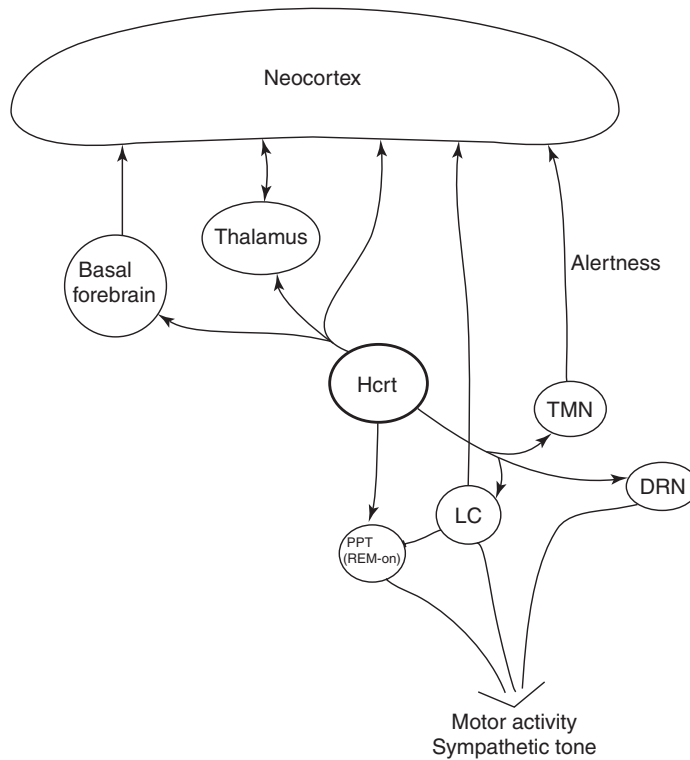

Figure 4.2 Hypocretin projections excite LC and DRN neurons to elevate muscle tone and TMN neurons to promote wakefulness. These components of the ascending reticular activating system, and the Hcrt neurons themselves, project to and stimulate thalamic and basal forebrain neurons, and all of these groups contribute to the depolarization of the cerebral cortex. The LC inhibits REM generator neurons in the PPT, which themselves receive Hcrt input.

all during REM [185, 219]. Each of these structures sends projections to a diverse array of targets in the forebrain, and their firing stimulates cortical arousal. The activity state of these groups of aminergic neurons is one of the features that distinguish wakefulness from REM. Additionally, and importantly, the hypocretin neurons project to other brain areas that have been implicated in arousal. For instance, the hypocretins, acting through Hcrtr2, excite cholinergic neurons of the basal forebrain which produce the cortical acetylcholine characteristic of the desynchronized EEG that is associated with wakefulness and REM [220]. Direct infusion of the hypocretins into the basal forebrain produces dramatic increases in wakefulness [146, 147, 221].

4.12.1 LH Neurons

Among the neurons of the perifornical lateral hypothalamus, 53% increase their firing rates during both wakefulness and REM but decrease their activities during slow-wave sleep [222]. An additional 38% of the neurons in this area are activated

only during the awake phase. The Hcrt neurons are among the latter group; that is, they are REM off. The off state is most likely established and maintained by inhibition by GABA interneurons, as infusion of the GABA_A antagonist bicuculline into the LH of spontaneously sleeping rats increased both wakefulness and *c-fos* expression by Hcrt neurons [223]. Electrophysiological studies on Hcrt neurons, identified in slice culture by their selective transgenic expression of green fluorescent protein and confirmed by appropriate agonists and antagonists, demonstrate that they are hyperpolarized via the action of glutamate (probably originating from local glutamatergic interneurons) acting at group III metabotropic receptors and NPY (from arcuate neurons) acting at Y1 receptors coupled to an inwardly rectifying potassium channel and are depolarized by glucagon-like peptide (GLP) from the brain stem acting through the GLP-1 receptor via a non selective cation conductance [224–227]. Hypocretin neurons express *c-fos* during the waking period (nighttime in rats) and *c-fos* expression is increased by sleep deprivation and methamphetamine [228]. The stimulant modafinil, which is commonly used to treat the drowsiness associated with narcolepsy, greatly elevates *c-fos* expression in hypocretin neurons [194, 229].

Hypocretin levels fluctuate circadianly, being highest during waking, and peptide concentrations increase as a consequence of forced sleep deprivation [125, 211, 230], suggesting that the hypocretins and the activity of the hypocretin neurons serve as pressures that oppose sleep. Interestingly, the amplitude of the circadian oscillation of hypocretin levels is decreased in patients with clinical depression, and treatment with the antidepressant sertraline partially restores the circadian oscillation observed in control subjects [211]. In the absence of environmental light cues, circadian cycling of Hcrt persists, but ablation of the SCN abolished cycling and reduced Hcrt in CSF [231, 232]. In squirrel monkeys, a species that consolidates its waking period into a single bout, limitation of locomotor activity did not have a great effect of CSF hypocretin [233]; however, in the Nile grass rat, a species that varies its distribution of day and night activity in the presence of a running wheel, wheel running affected the activity of Hcrt neurons [234]. In aged rats, peak CSF Hcrt levels are diminished, perhaps leading to increased napping associated with aging [235]. Other perturbations that increase *c-fos* expression in Hcrt cells include treatment with leptin, ghrelin, hypoglycemia, and food and sleep deprivation.

4.12.2 Noradrenergic Systems

The noradrenergic LC neurons fire constantly during wakefulness. In addition to their projections to the forebrain, these neurons send inhibitory projections to cholinergic REM-on (fire during wakefulness and more rapidly during REM but do not fire during slow-wave sleep) generator neurons in the PPT and LDT, which project to the pontine reticular formation [236, 237]. Hypocretin axons form synapses on these LC neurons, which express Hcrtr1 postsynaptically [49, 69]. Local administration of Hcrt1, but not Hcrt2, to the LC suppresses REM in a dose-dependent manner and increases wakefulness [69]. These effects are neutralized by an antibody that prevents binding of Hcrt1 to Hcrtr1. Administration of Hcrt1 increases the firing rate of noradrenergic LC neurons and induces expression of *c-fos* in these cells [69, 238] via depolarization involving both an augmented nonselective cation conductance and an inhibited potassium conductance [239]. Partial ablation of the

LC neurons via Hcrt2 targeting of the neurotoxin saporin (which kills LC neurons inefficiently due to the low affinity of Hcrt2 for Hcrtr1, the sole receptor in the LC) increased both sleep and limb movements during REM without eliciting cataplexy, consistent with the notion (see below on histaminergic systems) that Hcrt excitation of the LC during waking periods stimulates arousal and muscle tone and that Hcrt silence during REM serves to repress muscle activity controlled by the brain stem [240].

Hcrt terminals are also found on GABA neurons in the peri-LC [53, 241]. GABA inhibits LC neurons [242], suggesting that Hcrt has both direct excitatory effects on LC noradrenergic neurons and inhibitory effects on these same neurons via a feedforward circuit involving local GABA interneurons. Hcrt neurons are responsive to noradrenaline, thus providing a feedback loop between LC and Hcrt neurons. Whether the noradrenaline effect is excitatory, inhibitory, or state dependent is presently a matter of debate [58, 243, 244].

4.12.3 Serotonergic Systems

Serotonin neurons of the dorsal raphe in the brain stem are part of modulatory ascending and descending pathways that gate sleep–wake states [245]. These neurons receive input from Hcrt fibers which form synapses on them [246]. These serotonergic neurons express both Hcrtr1 and Hcrtr2 [247] and are equally excitable by Hcrt1 and Hcrt2, suggesting that signaling occurs through both receptors [248]. These neurons are sensitive to Hcrt excitation, which is of slow onset and long duration, during slow-wave or REM sleep, but not during wakefulness during which these neurons are already maximally active [249]. Hypocretins increase the activity of serotonin cells in the dorsal raphe via a PKC-mediated influx of Ca^{2+} through L-type calcium channels [70, 71, 250].

Studies utilizing hypothalamic slices from transgenic mice expressing green fluorescent protein exclusively in Hcrt neurons demonstrate that these neurons are hyperpolarized by serotonin via a mechanism involving an inwardly rectifying potassium channel and that the hyperpolarization is blocked in the presence of the 5-HT_{1A}-selective antagonist WAY100635 [43]. ICV administration of WAY100635 to mice in the latter part of night increased locomotor activity, but this effect was not observed in mice in which Hcrt neurons were ablated [43]. Although direct reciprocal inputs from dorsal raphe serotonergic neurons to Hcrt neurons in the LH have yet to be demonstrated, the above findings are consistent with activity-dependent increase in serotonin in the LH contributing to waning Hcrt neuronal activity as the sleep period approaches.

4.12.4 Histaminergic Systems

Histamine neurons are wake-active neurons located exclusively in the TMN of the hypothalamus. They project to the hypothalamus, basal forebrain, thalamus, cortex, and brain stem. TMN neurons express Hcrtr2 and receive inputs from Hcrt-containing axons. Both Hcrt1 and Hcrt2 depolarize histaminergic TMN neurons by activation of an electrogenic sodium–calcium exchanger and a Ca^{2+} current associated with a small decrease in input resistance and increases in spontaneous firing [77]. Knockout mice deficient in histamine receptor 1 are impervious to

hypocretin administration, suggesting that at least some of the effects of the Hcrt are caused by release of histamine and activation of postsynaptic H_1 receptors [78, 251, 252]. The concentrations of the mRNAs for histamine receptors decrease with age in the mouse brain, as does *Hcrtr2* mRNA, possibly accounting the diminishment of alertness and quality of sleep associated with aging [253].

One of the features of narcolepsy is cataplexy, which is a sudden loss of skeletal muscle tone, often triggered by emotions or laughter. During cataplectic episodes, although narcoleptic individuals enter a REM-like state of muscle atonia, they are awake, aware of their environment, and otherwise conscious. Thus, vigilance and the control of muscle tone are dissociated in this pathological state. Studies in *Hcrtr2*-deficient narcoleptic dogs [254] showed that histamine neurons, in contrast to noradrenergic and serotonergic REM-off cell groups, are active during cataplexy. Activity of histamine neurons is thus linked to the maintenance of waking, whereas that of noradrenergic and serotonergic neurons is tightly coupled to the maintenance of muscle tone in waking and its loss in REM sleep and cataplexy.

4.12.5 Dopaminergic Systems

The dopaminergic neurons of the VTA and ventral periaqueductal gray do not change their activity greatly throughout the sleep–wake cycle. Dopaminergic and GABAergic neurons in the VTA receive inputs from Hcrt neurons of the LH [170]. The hypocretins excite these neurons via Ca^{2+} -, PLC-, and PKC-dependent pathways, promoting arousal [89]. Interestingly, administration of dopamine agonists to the VTA of *Hcrtr2*-deficient dogs aggravated cataplexy, suggesting that this structure contributes to inhibition of muscle tone during REM [255].

4.12.6 Cholinergic Systems

The hypocretin neurons project to cholinergic brain stem REM-on neurons, including those in the LDT and the pontine reticular formation whose projections contribute to cholinergic tone in the forebrain. This tone is elevated during both wakefulness and REM leading to desynchronization of the EEG. Cholinergic tone is low in slow-wave sleep and during which acetylcholine activity is further inhibited by the sleep-promoting peptide of forebrain interneurons, cortistatin [256], contributing to the slow-wave synchrony of the EEG. In contrast *Hcrt1* enhances cortical release of acetylcholine [257]. Local injection of *Hcrt1* into the LDT of freely moving cats increases wakefulness and decreases the number of REM episodes but does not influence episode length [220], suggesting that the hypocretin system influences the gate (or switch) to REM by reducing the firing rates of the brain stem REM-on cells but does not itself operate during REM. This and the fact that deficiencies in the hypocretin system lead to increases in REM episodes make it more likely that action at REM-on structures by hypocretin occurs only during waking periods [258]. The role of hypocretin in regulating the REM gate is a complex one in that, paradoxically, the REM-on structures receive both indirect hypocretin-initiated inhibitory signals from REM-off cells and direct projections from the hypocretin neurons themselves and therefore must decide on how to respond to this push–pull pressure in different scenarios.

The midline and intralaminar thalamic neurons coordinate activity levels broadly across cerebral cortex and support attention and awareness. *Hcrt1* and *Hcrt2*

selectively depolarize midline–intralaminar thalamic neurons and not sensory thalamic neurons [83]. Midline–intralaminar nuclei express Hcrtr2 [60, 61, 259]. The hypocretins excite arousal-related cholinergic neurons in the basal forebrain by suppressing the activity of an inwardly rectifying potassium channel [80, 260].

Hcrt neurons project directly to the cerebral cortex in addition to projecting onto subcortical relay neurons. In the cortex, Hcrt fibers are distributed through all layers, although most densely in the deeper layers. In layers 1–6a, hypocretins have no direct effect upon cortical neurons, although there are indirect effects through presynaptic terminals of inputs [81]. Hcrt has a direct postsynaptic depolarizing action upon cortical neurons located exclusively in layer 6b that is mediated by Hcrtr2. Layer 6b neurons project diffusely to layer 1 of surrounding cortical areas [261], allowing cortical activation to propagate widely.

Hcrt fibers form synapses on cholinergic neurons in the medial septum–diagonal band of Broca [79]. Both Hcrt1 and Hcrt2 activate these neurons via a mechanism that involves both an inwardly rectifying potassium channel and a probable sodium–calcium exchanger [79]. These neurons, which express Hcrtr2 and show axon degeneration in Hcrtr2-deficient dogs, project to the hippocampus, where they influence local theta rhythm and its associated memory functionality.

4.13 HYPOCRETINS INTEGRATE AROUSAL, FEEDING BEHAVIOR, AND MOTIVATION

Hypocretin peptides excite LC and dorsal raphe neurons to elevate muscle tone and TMN neurons to promote wakefulness. These components of the ascending reticular activating system, and the Hcrt neurons themselves, project to and stimulate thalamic and basal forebrain neurons, and all of these groups contribute to the depolarization of the cerebral cortex, including layer 6b neurons (Fig. 4.2). Arousal-related signaling occurs through both Hcrtr1 and Hcrtr2. The involvement of both receptors is consistent with the more severe phenotype of the double receptor knockout mice compared to either single receptor knockout [196]. It is also consistent with the observation that sporadic cases of canine narcolepsy associated with lower or undetectable CSF hypocretin are more severe than are cases with the Hcrtr2 deficiencies alone [262]. Nevertheless, Hcrtr2 plays the more prominent role in raising arousal levels.

These peptides also have diverse effects on brain reward and autonomic systems related to stress that serve to increase motivated behaviors, among those feeding. The relation to feeding is a complex one. Acute administration of Hcrt to sleeping rats increases food consumption. However, patients with narcolepsy have chronically low concentrations of the hypocretins but have an increased likelihood of being obese despite reduced daily calorie intake [263–265], and in children, plasma Hcrt concentrations are negatively correlated with body mass index [266]. Similarly, although hypocretin knockout mice are hypophagic, they do not have lower weights than the unaffected controls. Mice depleted of hypocretin neurons fail to show increased alertness in response to fasting, suggesting that the hypocretinergeric system senses changes in metabolic signals and drives the circuitry involved in arousal. Rather than considering the hypocretins to be orexigenic, they appear to serve as a counterregulatory response to obesity.

5.1 INTRODUCTION

Snake venom and skin secretion from frogs have been rich sources for isolating biologically active regulatory peptides. Prokineticins (PKs) are no exceptions. The history of PKs can be traced back to more than 20 years ago, when Joubert and Strydom purified a 77-amino-acid peptide from black mamba venom with unknown biological functions [1]. This peptide was named MIT1, and the first biological function associated with this family of peptides was its ability to stimulate the contraction of gastrointestinal smooth muscle [2]. The real expansion of the field started when Kreil's group purified and sequenced a frog protein named Bv8 [3]. This frog protein was shown to be highly similar to the snake protein and possess the same potent contractile activity on gastrointestinal smooth muscles [3]. The mammalian homologs for Bv8 and MIT1, with consensus name of PKs, were subsequently identified by three groups [4–6]. Over the last few years, a spectrum of biological functions has been assigned to this new family of regulatory peptides (Fig. 5.1).

5.2 RECEPTORS FOR PROKINETICINS

Three groups independently identified two closely related G-protein-coupled receptors for PKs, prokineticin receptor 1 (PKR1) and prokineticin receptor 2 (PKR2) [7–9]. These receptors are unusually conserved with over 80% amino acid identity between them. Recombinant PK1 and PK2 have been shown to activate both receptors at nanomolar concentrations when exogenously expressed in Chinese hamster ovary (CHO) cells. In PKR-transfected cell lines, neurons, and specific endothelial cells, activation of prokineticin receptors stimulates calcium mobilization, phosphoinositol turnover, mitogen-activated protein kinase (MAPK), and Akt kinase pathways [7–10]. While the stimulation of calcium mobilization upon receptor activation is dependent on G_q , activation of the MAPK pathway is pertussis toxin sensitive, suggesting that PKR may also couple to other G proteins such as G_i . Activation of the G_i signaling may also be related to the function of PK in cell proliferation, migration, and survival.

Reverse transcriptase polymer chain reaction (RT-PCR) indicates that PKR1 is widely distributed in the periphery, including the stomach, small intestines, colon, spleen, pancreas, and peripheral leukocytes [7–9]. Although both receptors are expressed in the gastrointestinal (GI) system, PKR1 is more abundantly expressed in the stomach and intestine, suggesting that it may be the major receptor mediating the actions of PKs in GI motility. Whereas PKR1 is more widely expressed in the periphery, *in situ* analysis indicates that PKR2 is the more dominantly expressed receptor in the adult brain. PKR2 messenger RNA (mRNA) can be detected throughout the adult brain, including areas in the hypothalamus and its primary output targets, as well as the olfactory ventricular regions and the limbic system [11, 12]. RT-PCR also indicates that PKR are expressed in various endocrine tissues, including thyroid, pituitary, adrenal gland, testis, and ovary [7–9]. The presence of both receptors in several endocrine and nonendocrine tissues and their activation of the MAPK pathway may be related to the function of PKs in angiogenesis, cell proliferation, migration, and survival [6]. Furthermore, Negri et al. [13] revealed the presence of both PKRs in the dorsal root ganglion and the spinal cord, and thus the effects of Bv8 on nociceptive threshold may result from the activation of PKRs in these sensory neurons.

5.3 STRUCTURAL DETERMINANTS REQUIRED FOR FUNCTIONAL ACTIVITIES OF PROKINETICINS

The mammalian prokineticins (PK1 and PK2) have about 45% amino acid identity between them and also to their nonmammalian counterparts (MIT1 and Bv8). Sequence analysis indicates that both the human and mouse PKs contain three exons with distinct N-terminal and C-terminal domains [14]. The first exon encodes a signal peptide and the first five amino acids in the N-terminus, and exons 2 and 3 encode the cysteine-rich domains. Interestingly, PKs and their amphibian homologs exhibit certain conserved characteristics in their amino acid sequences. This includes the first six amino acids in the N-terminal domain (AVITGA) and the 10 cysteine residues with identical positions, which are predicted to form five pairs of disulfide bonds [5]. These conserved characteristics suggest the potential functional importance of

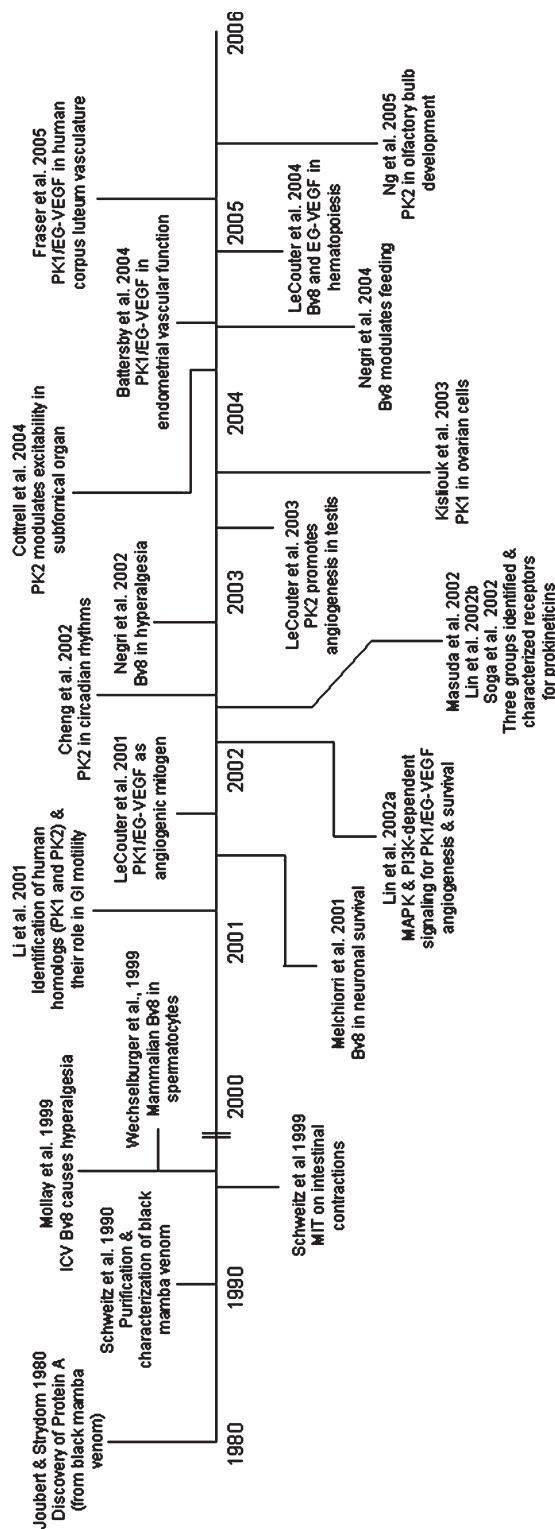

Figure 5.1 Timeline of discovery of biological functions for prokineticins/Bv8/EG-VEGF.

these residues. To delineate the structural elements that are essential for the bioactivities of PKs, we have investigated the structural–functional relationship of PKs by generating recombinant proteins that contain substitutions, deletions, or insertions of amino acid in the N-terminal or the C-terminal [14]. These mutant proteins were then tested for their agonist activities by measuring their ability to mobilize intracellular calcium and/or induce ileum contractions. Substitution or addition of any of the six amino acid residues in the N-terminus rendered the PKs inactive, indicating the importance of these N-terminal residues for activating PKRs. Mutation studies have also demonstrated that the conserved cysteine residues are also critical for their bioactivities, although residue changes in the C-terminus are more tolerable. Chimeric proteins with exchanged cysteine-rich domains between PK1 and PK2 remain active and possess functional activities comparable to PK1 or PK2. Intriguingly, two of the N-terminus mutants with either substitution or addition of only one amino acid generated mutant PKs that possess potent antagonist activity. A splice variant of PK2 that contains an extra 21-residue insertion in the C-terminus is also biologically active, although with a much lower potency. A recent study reported that there might be further protease processing of this PK2 variant, which yields another peptide that may specifically activate PKR1 in stimulating adenylate cyclase [15, 15a]. It is likely that PK ligands may be more complicated than originally thought.

5.4 PROKINETICIN AS REGULATOR OF SMOOTH MUSCLE CONTRACTILITY

The motility of the GI tract is regulated by classical neurotransmitters, neuropeptides, and circulating hormones. Schweitz et al. [2, 16] had purified MIT1 from snake venom and demonstrated that it potently stimulated contraction of the guinea pig ileum. A protein of similar size that has greater than 40% identity with MIT1 has also been purified from frog skin secretion [3]. This frog protein is named Bv8 and is also found to cause potent contractions of the GI smooth muscles. In an attempt to search for the mammalian homologs of the frog Bv8 and snake MIT1, we have isolated and characterized two human complementary DNAs (cDNAs) that encode the homologs for snake MIT1 and frog Bv8 [5]. We have produced recombinant human PKs and demonstrated that these mammalian proteins also stimulate contractions of the GI smooth muscles with similar potency. To reflect their potent actions on GI contractility, we have named these proteins “prokineticins.” Whereas it is still unclear whether the effect of PKs on GI smooth muscle cells are pharmacological or physiological, subsequent *in vivo* studies have demonstrated that both PKs stimulate the GI transit (Owyang et al., unpublished study, Zymogenetics patent filing). Although the cell identities that express PKs in GI tissues remain unknown, ligand binding studies had revealed the presence of high-affinity receptors for PKs in the GI smooth muscle cells [5].

5.5 PROKINETICINS AND PAIN PERCEPTION

The first observation that linked PKs to nociception was reported by Mollay et al., who observed that administration of Bv8 into the rat brain induced a marked

hyperalgesic response [3]. Based on this initial finding and other preliminary results which indicated that pituitary and circulating leucocytes express high level of PK2 [7–9, 13], the same group speculated that these proteins might function as inflammatory agents. In a further study, Negri et al. assessed the effects of frog Bv8 on the nociceptive threshold to thermal and mechanical stimuli using various routes of administration [13]. Intravenous, subcutaneous and intrathecal injections of Bv8 all produced intense systemic nociceptive sensitization to mechanical and thermal stimuli applied to tail and paws [13]. Topical delivery of Bv8 also decreased the nociceptive threshold. To elucidate whether the hyperalgesic effects of Bv8 may be mediated through PKRs, they have examined the localization of PKRs in the rat dorsal root ganglia (DRG) and the spinal cord. Both PKR1 and PKR2 mRNAs are expressed in the DRG and the spinal cord [13]. It was also demonstrated that Bv8 can bind to these PKRs on the DRG neurons and the spinal cord with high affinity. Furthermore, functional assays indicated that Bv8 was able to mobilize calcium in cultured rat DRG neurons in a dose-dependent manner [13]. These data suggest that Bv8 or its mammalian homologs sensitize peripheral or central nociceptors via activation of PKRs in the DRG or spinal cord.

5.6 REGULATORY FUNCTION IN CIRCADIAN CLOCK OUTPUT

The suprachiasmatic nucleus (SCN) in the anterior hypothalamus is the primary mammalian circadian clock that regulates daily rhythms of diverse physiology and behavior, including sleep–wake cycle, blood pressure, heart rate, body temperature, and energy metabolism [17]. While the understanding of the molecular mechanism of the circadian clockwork has emerged in the last decade [17, 18], little is known about the mechanism by which the circadian clock transmits timing information to control physiology and behavior. In an attempt to study the function of PKs in the central nervous system, we have mapped the mRNA distribution of the PKs and their receptors in the mouse brain using *in situ* hybridization analysis. Our initial characterization revealed that PK2 mRNA is highly expressed in the SCN in an oscillating fashion, with high levels during the day and low levels or undetectable at night [11]. Subsequent molecular and behavioral studies demonstrated that PK2 is a candidate output signaling molecule for circadian locomotor rhythms [11]. The PK2 oscillation in the SCN is maintained in animals under normal 12 h light–12 h dark as well as under constant darkness, indicating that this PK2 oscillation is driven by the endogenous circadian clockwork [11]. As Clock and Bmal1 are the positive elements of the clockwork, these transcription factors heterodimerize and bind to CACGTG sequences known as E-box to activate transcription of other clock or clock-controlled genes [17, 18]. Both the human and mouse PK2 promoter contains four E-boxes within the first 2 kb upstream of the transcription start site [11]. *In vitro* reporter gene assay indicated that PK2 transcription is tightly regulated by clockwork gene products through activation of the E-boxes residing in its proximal promoter. These *in vitro* findings were supported by *in vivo* studies which demonstrated that PK2 mRNA expression in the SCN is completely absent or blunted in mutant mice that lack functional clockwork. *In situ* hybridization revealed that the receptor for PK2 is expressed in primary SCN output target areas, further supporting the role of PK2 in circadian rhythms. To elucidate whether PK2 plays a role in

circadian-regulated behavior, we have tested the effects of PK2 on locomotor wheel-running activity, as this is one of the most common ways to study circadian rhythms. Intracerebroventricular delivery of PK2 into the lateral ventricle during subjective night, when endogenous PK2 is low, inhibited the nocturnal wheel-running activity of rats [11]. These results demonstrated that PK2 is a candidate output molecule that transmits circadian behavioral rhythms from the SCN clock.

While the direct genetic analysis of PK2 deficiency on circadian rhythm has yet to be determined, Morton et al. have observed a correlation between increased daytime activity and reduced SCN expression of PK2 molecular rhythm in a transgenic model of Huntington's disease [19]. As PK2 is a SCN output molecule regulating circadian locomotor behavior, this finding suggests that the reduced PK2 rhythm may contribute to the sleep disturbances and abnormal circadian behavior seen in this strain of transgenic mice. Recently, the molecular rhythm of PK2 in the SCN of a diurnal rodent has been reported [20]. Similar to the oscillation pattern observed in mouse, PK2 mRNA in the SCN of *Arvicanthis niloticus* was also rhythmically expressed, with peak levels in the morning, preceding the peaks of *Per1* and *Per2* [20]. Thus, the phase of PK2 expression in the SCN of diurnal rodent is similar to that of nocturnal rodents, consistent with a growing body of evidence suggesting that the key to diurnality lies downstream of the SCN circadian clock.

As we have previously observed that nocturnal light pulses can rapidly induce PK2 expression in the SCN, we have further investigated the possibility that PK2 is under the dual regulation of core clockwork and the light. Using a common model for jet lag, we examined how PK2 responds to abrupt shifts of light–dark cycles (phase delays or phase advances) [21]. We observed that PK2 expression exhibits transients in response to phase advances but entrains rapidly to phase delays. Intriguingly, this differential pattern of PK2 expression during time shifts is consistent with the circadian phenomenon that animals and humans adjust rapidly to time delays but slowly to advances [22, 23]. This study further provided additional supporting evidence for PK2 as an output signaling molecule from the SCN. We have also made another interesting observation that light can directly regulate PK2 in the absence of functional circadian clockwork. Studies with cryptochrome double-knockout mice revealed that a light-regulated low-amplitude PK2 rhythm exists in these mice that lack functional circadian oscillators [21]. These studies suggest that PK2 is controlled by dual mechanisms: dominantly by the circadian oscillators but also directly by light. Evolutionarily, this could indicate that PK2 may evolve before the circadian timing system becomes internalized in the brain.

5.7 FUNCTIONS IN INGESTIVE BEHAVIOR

Daily ingestive behaviors such as feeding and drinking are examples of circadian-regulated processes, as rodents consume over 80% of food during the dark period [24]. Since PK2 has been shown to be one of the first circadian output molecules that regulate circadian locomotor behavior, the expression patterns of PK2 also suggest that PK2 may play a role in feeding and drinking, as PK2 mRNA is expressed in areas such as the arcuate nucleus, paraventricular hypothalamic nucleus, and subfornical organ, which are primary regions that regulate ingestive behavior [11, 24, 25]. Thus, it is possible that PK2 could also modulate other circadian behavior,

such as feeding and drinking. To test this hypothesis, Negri et al. examined the effects of Bv8 on spontaneous food and water intake and demonstrated that Bv8 and PK2 modulate these ingestive behaviors in rats [26]. They showed that intracerebroventricular delivery of Bv8 suppressed diurnal and nocturnal feeding as well as deprivation-induced and NPY-stimulated feeding [26]. Bv8 injected into the lateral ventricle also stimulated drinking during daytime. When Bv8 is microinjected into the arcuate nucleus, Bv8 suppressed feeding in normal fed and fasted rats without affecting drinking. Interestingly, microinjection of Bv8 into the subfornical organ, an area in the brain that is known for regulation of thirst [25], stimulated drinking. It has recently been shown that PK2 activates and depolarizes the dissociated neurons of the subfornical organ [27]. Similar to the actions of Bv8, preliminary results showed that the mammalian recombinant PK2 also produced potent anorexigenic response in rats [26], our unpublished observations). Although the current target and pathway of Bv8/PK2 in regulating these ingestive behaviors are still unclear, it is possible that this effect may be related to the role of PK2 as a circadian output molecule, as the SCN is known to regulate diverse physiological processes, including feeding and drinking [24]. These findings indicate that PK2 may be a regulatory molecule for ingestive behavior and further expanded the versatile function of prokineticins in physiology and behavior.

5.8 FUNCTIONS IN ANGIOGENESIS AND REPRODUCTION SYSTEM

During the last decade, significant progress has been made in the identification of molecules that regulate vascular growth, a crucial process for many diverse biological processes, including embryonic development, reproductive functions, tumorigenesis, and wound healing. In particular, vascular endothelial growth factor (VEGF) and the Tie2 ligands (angiopoietins) have been shown to play critical roles in the proliferation of endothelial cells and the assembly of blood vessel wall [28]. However, these molecules are widely expressed and show little tissue specificity in their angiogenic properties and thus cannot account for the tissue-specific angiogenesis. When screening a library of human secreted molecules for their ability to induce proliferation in primary bovine adrenal cortex-derived capillary endothelial [angiotensin-converting enzyme (ACE)] cells, LeCouter et al identified one molecule that was capable of inducing strong mitogenic response [6]. Due to its tissue-specific angiogenic nature, this molecule is named endocrine gland-derived (EG) VEGF. Delivery of EG-VEGF in ovary elicited potent angiogenesis and cyst formation, and this effect is absent when delivered to cornea or skeletal muscles. Similar to VEGF, EG-VEGF also has a HIF-1 binding site, and its expression is induced by hypoxia. Sequence analysis revealed that EG-VEGF is the same molecule as PK1 [5, 6].

Following the initial finding of PK1 as the first example of a tissue-specific angiogenic factor, LeCouter et al. also pursued whether a PK1-related molecule, PK2, also plays a role in angiogenesis. PK2 has been shown to induce proliferation, survival, and migration of ACE cells, and its expression is also hypoxia inducible [29]. Interestingly, PK2 is highly expressed in the testis, and adenoviral delivery of PK2 into mouse testis resulted in a potent angiogenic response. This angiogenic effect is likely to be mediated through PKR, as both PKRs are expressed in the vascular endothelial cells of the testis [29]. The potent angiogenic effect of PKs suggests their

role in regulating the proliferation of blood vessels in reproductive organs. In the following years, several groups have further examined the role of PKs in reproductive organs, as the process of angiogenesis is crucial for reproductive functions [30–32]. Battersby et al. [31] demonstrated that both PK receptors were localized in the glandular epithelial, stromal, and endothelial cells in the human endometrium. Quantitative PCR revealed that PK1 expression, but not PK2, was elevated during the secretory phase of the menstrual cycle, and this PK1 elevation is induced by treatment with progesterone [31]. Interestingly, two putative progesterone receptor binding sites are found in the promoter of PK1, suggesting that the increase in PK1 expression may be caused by the direct action of progesterone on PK1 transcription [31]. Another group examined the regulation of VEGF and PK1 in human ovarian granulosa cells and demonstrated that both of these angiogenic factors are expressed in these cells but their expression is inversely regulated [30]. It is interesting to note that in these cells PK1 expression is stimulated by forskolin but downregulated by chemical hypoxia and thrombin [30]. This opposite effect may be due to the cell type that is expressing PK1. Frazer et al. [32] recently demonstrated that PK1 is localized in the human corpus luteum and its expression is increased throughout the luteal phase. Unlike the increase of PK1 in the human endometrium, the expression of PK1 in human corpus luteum is increased by treatment with human chorionic gonadotropin but not influenced by progesterone [32]. Together these studies indicate that PKs have a physiological role in reproductive function by regulating endothelial or other cell types.

Several groups have also studied the expression of PK1 in ovarian diseases such as polycystic ovary syndrome (PCOS) and ovarian tumors [33, 34]. A prominent feature of PCOS is an increased angiogenesis, leading to hyperplasia and hypervascularity of the ovarian theca interna and stroma. As PK1 has a selective mitogenic effect for the endothelium of steroidogenic glands [6], Ferrara et al. [33] examined the expression of PK1 in human PCOS and normal ovary specimens. In PCOS ovaries, strong expression of PK1 mRNA was detected in theca interna and stroma, whereas VEGF mRNA was mainly expressed in the granulosa cell layer [33]. This complementary expression pattern is an amplification of the pattern seen in normal ovaries. These findings indicate that PK1 and VEGF may play a complementary function for ovarian angiogenesis and possibly cyst formation. Another group focused on examining the expression of PK1 in different stages of ovarian tumor samples [34]. Although PK1 mRNA was detected in all ovarian carcinomas, including benign, low malignant potential neoplasms, or stage I ovarian cancer, no significant differences were identified between these tumor types. It is interesting to note that PK1 mRNA level was also lower in these tumor samples when compared to normal premenopausal ovaries. During the later stages of these ovarian carcinomas, a significant further decrease of PK1 mRNA was observed [34]. In contrast to VEGF, PK1 mRNA levels did not correlate with clinical outcome in advanced ovarian carcinoma. These results suggest that PK1 may only play a marginal role in promoting angiogenesis in advanced ovarian carcinoma.

5.9 FUNCTION IN HEMATOPOIESIS

Since PK1 and PK2, as well as their receptors, are known to express in bone marrow and other hematopoietic organs [5], LeCouter et al. [35] investigated a possible role of

PK1 and PK2 in hematopoiesis. Detailed expression analyses indicated that both PKR1 and PKR2 are expressed in hematopoietic stem cells and specific mature blood cells, including lymphocytes. Interestingly, PK2 is also highly expressed in infiltrating cells at sites of inflammation, predominantly in neutrophils, and the expression of PK2 and both PKRs are induced in monocytes upon exposure to the endotoxin lipopolysaccharide (LPS) [35]. Le Couter et al. [35] demonstrated that PK2 can induce monocyte migration and this migratory signaling is pertussis toxin sensitive, suggesting that G_i may be the primary G protein mediating this effect. Furthermore, PK2 also increases the number of colony-forming units granulocytic and monocytic in cultures of the human or mouse hematopoietic stem cells. Systemic injection of PK2 also increases the number of leukocyte, neutrophil, and monocyte counts. In addition to the proliferative effects of PK2 on these immune cells, PK2 also promotes their survival, as adenoviral delivery of PK2 increased the survival of hematopoietic cells in 5-fluorouracil-induced injury. This is consistent with the previous finding that Bv8 supports the survival of cortical and cerebellar granule cells in cultures against apoptosis and excitotoxic death [36]. Together, these studies suggest that PK2 may function as a monocyte chemoattractant and a hematopoietic cytokine that promotes survival and modulates the innate and adaptive immune systems.

5.10 FUNCTION IN NEURODEVELOPMENT

In mammals, neurogenesis occurs mainly during embryonic to early postnatal stages. However, there exists persistent neurogenesis in certain regions of adult mammalian brains, including the olfactory bulb (OB) and the dentate gyrus (DG) of the hippocampus [37, 38]. New neurons are continuously generated in the OB from progenitor cells that reside in the subventricular zone (SVZ) of the lateral ventricle, where they proliferate and migrate through the rostral migratory stream (RMS) to the OB to form granular and periglomerular cells [39–41]. Although this SVZ–OB pathway and the timing of neurogenesis have been well documented, the mechanism of this guided process is still not well understood. We have recently demonstrated that PK2 functions as a chemoattractant for SVZ-derived neuronal progenitors and is essential for the normal development of OB architecture [12]. In situ hybridization revealed that the expression of PK2 and its receptor complement each other in the OB, with PK2 expressed in the mature granular and periglomerular layers of the OB whereas its receptors (PKR1 and PKR2) are expressed in the immature ependyma and subependymal layers of the olfactory ventricle (OV). In vitro and in vivo studies demonstrated that PK2 serves as a chemoattractant for the SVZ-derived neuronal precursors. Migration assays using Transwell assay system and collagen gel matrices indicated that PK2 can stimulate migration of neuronal progenitors from the RMS in both adult and postnatal rats, and this migration is directional and can be inhibited by the PK antagonist A1MPK1 [12]. It is also likely that PK2 may act as a detachment signal for the chained migrating neuronal precursors, as addition of PK2 in SVZ explant cultures increases the number of cells migrating out of the explants and disperses the cells from migrating chains to individual cells. The critical role of PK2 in OB development was demonstrated by genetic studies. PK2 deficiency in mice resulted in abnormal development of OB, including dramatic reduction in OB size and the loss of normal OB layer architecture [12]. As PKs have been previously

Figure 5.2 Known biological functions of prokineticins. Prokineticins PK1 and PK2 are a pair of cysteine-rich secreted molecules that exert their functions via activation of two G-protein-coupled receptors (PKR1 and PKR2). Activation of prokineticin receptors leads to multiple signaling pathways, including mobilization of intracellular calcium, phosphoinositol turnover, and mitogen-activated protein kinase pathways. Prokineticins have been shown as versatile molecules regulating multiple biological processes, with some selective pairing of ligand and receptor. In particular, prokineticins stimulate gastrointestinal smooth muscle motility and induce hyperalgesia. Prokineticins have also been shown to function as angiogenic mitogens that act selectively on endothelial cells from endocrine glands or reproductive organs. Furthermore, PK2 has been shown as a candidate output signaling molecule that regulates circadian behavior, including locomotor activity and feeding behavior. More recently, PK2 has been shown as a critical chemotactic molecule that is essential for the migration of OB neurons.

demonstrated as angiogenic factors, our findings of PK2's role in neurogenesis support that signaling commonality between angiogenesis and neurogenesis.

5.11 PERSPECTIVES

Over the last few years, PKs have evolved as a pair of signaling peptides that regulates diverse functions ranging from GI motility, angiogenesis, and hematopoiesis to circadian clock output and ingestive behavior (Fig. 5.2). It is interesting to note that these diverse functions may be classified into two general categories: cell excitability and cell motility. It appears that the regulatory function of PKs in GI smooth muscle, circadian clock output, and ingestive behaviors may be related to the activation of PKRs in the target cells, which results in enhanced cell excitability, whereas the function of PKs in angiogenesis, hematopoiesis, and neurodevelopment seems to be more closely linked to the effect of PKs in modulating cell motility. Recently, in collaboration with the Ferguson group, we have directly demonstrated that PK2 activates and depolarizes the neurons of the subfornical organ and the paraventricular hypothalamic nucleus [27, 42]. Another theme that is emerging from these studies is that the transcripts of PKs are dynamically regulated. Without a doubt, the current known functions of the PK system are likely to be just the tip of an iceberg.

6.1 INTRODUCTION

Sedatives and hypnotics are general terms to represent a class of drugs that induce a general depression of central nervous system (CNS) function. As will be discussed below, there are a number of different types of sedatives/hypnotics. They have evolved over the years from what could be defined as broad-spectrum CNS depressants such as the barbiturates through the much more specific agents (in terms of their molecular targets) [1]. The vast majority of sedatives/hypnotics have their clinical effect by modulating the γ -aminobutyric acid type A (GABA_A) receptor system in the brain. They are exemplified by the ubiquitous benzodiazepines, such as diazepam

(Valium). As such, GABA_A receptor modulators will be the primary focus of this chapter.

The clinical need for drugs classed as hypnotics/sedatives is clear. Use of drugs such as the benzodiazepines as sedatives in clinical practice is widespread [2]. They are used in surgery preoperatively, and indeed in minor operative procedures, to induce myorelaxation and sedation as well as in the emergency room as acute relaxants. Beyond these acute uses, as would be expected, there is widespread and growing use as treatment for insomnia [3, 4]. Insomnia can be defined as difficulty in sleeping or disturbed sleep patterns leaving the perception of insufficient sleep. Insomnia is divided generally into two main categories: sleep onset insomnia (the inability to fall asleep naturally) and sleep maintenance insomnia (the inability to stay asleep or to resume sleep after waking in the middle of the sleep cycle). Insomnia can be further categorized as acute or chronic. Acute insomnia is self-limiting, lasting a few weeks or months and ending without being treated. Chronic insomnia lasts longer than three months. The prevalence of insomnia is unknown but may well affect at least half the adult population [5]. Because insomnia can be a symptom of an underlying illness, stress, trauma, and so on, its incidence varies with regard to age, sex, and severity of the predisposing condition.

In this chapter we will describe what we currently know about the GABA_A receptor, the site of action of the vast majority of currently available sedatives/hypnotics. We will then describe what is known about the neural substrates which are modulated by sedatives/hypnotics to give their clinical effects. Finally we will describe the range of sedative/hypnotic drugs, from barbiturates through to non-selective benzodiazepines, through to subtype selective benzodiazepines and ending with gaboxadol, a selective extrasynaptic GABA_A receptor agonist.

6.2 GABA_A RECEPTORS

6.2.1 Structure

Inhibitory neurotransmission in the adult mammalian CNS is primarily mediated through the GABAergic system [6]. Neurotransmitter receptors for the neurotransmitter GABA are divided into the ionotropic GABA_A and the metabotropic GABA_B, and it is the former that is the topic of this section. GABA_A receptors mediate the majority of fast inhibitory neurotransmission. After GABA is released from the presynaptic terminals, it rapidly diffuses across the synapse and binds to the receptor. Binding of GABA to the two cognate sites on the extracellular surface of the receptor leads to the very rapid (millisecond) opening of the integral ion channel which gates chloride ions [7]. These pass through the ion channel into the postsynaptic cell, causing a hyperpolarization. The flow of ions is terminated by dissociation of the GABA and inactivation of the ion channel. GABA_A receptors are members of the cysteine loop ligand gated ion channel superfamily exemplified by the nicotinic acetylcholine receptor from *Torpedo* electroplax. They are pentameric hetero-oligomers assembled like staves of a barrel around a central ion channel [8]. The topology of the subunits is such that each has a large extracellular domain, four transmembrane domains (M₁–M₄), and a so-called large intracellular loop between M₃ and M₄ [9]. The latter contains several phosphorylation sites which are known to

regulate receptor function and turnover [10]. The pore of the ion channel itself is formed from the M₂ domains of the five subunits. To date, 19 GABA_A receptor subunits (α_1 – α_6 , β_1 – β_3 , γ_1 – γ_3 , δ , ϵ , θ , π , ρ_1 – ρ_3) have been identified [11]. Diversity is further increased by the existence of alternatively spliced versions for a number of these subunits [12]. Each of the subunits has its own unique pattern of expression throughout the CNS, and indeed specificity exists at the level of cell type and probably at the level of the synapse [13]. Clearly the number of potential permutations of assembly of these various subunits into pentameric hetero-oligomers is enormous. Indeed, the question of which subunit combinations actually exist in the mammalian CNS has been a significant challenge and has yet to be completely clarified. It is clear that as techniques have evolved, the more combinations have been identified. It is an interesting point of conjecture as to when the approaches become so refined that they identify subunit assemblies that are errors in the cell's assembly processes. It seems reasonably clear that the composition of receptor subtypes is determined by the regional and cellular distribution of subunits and also by certain rules that govern assembly. Quantitatively, the majority of GABA_A receptors contain a γ_2 subunit. It is almost universally agreed on that the most abundant receptor subtype has the composition $\alpha_1\beta_2\gamma_2$ [14]. The other most abundant receptor subtypes are composed of $\alpha_2\beta_3\gamma_2$, $\alpha_3\beta_3\gamma_2$, $\alpha_5\beta_n\gamma_2$, and $\alpha_6\beta_n\gamma_2$. There is also evidence that some GABA_A receptor subtypes contain two different α subunits [15, 16]. The subtype $\alpha_6\beta_n\gamma_2$ is almost exclusively expressed in cerebellar granule cells [17]. The subtype $\alpha_4\beta\gamma_2$ is a relatively minor population [14]. The δ subunit is thought to be largely assembled with α_4 or α_6 (and a β subunit) [18, 19]. While the latter are restricted to cerebellar granule cells, the former are expressed more widely in hippocampal, cortical and, thalamic regions. The receptor subtype $\alpha_4\beta\delta$ is increasingly interesting and is discussed further below in the context of gaboxadol. Far less is known about GABA_A receptors containing γ_1 , γ_3 , ϵ , and π other than these subunits likely substitute for the γ_2 subunit in the receptor complex [20]. Receptors containing ϵ and π certainly are of low abundance with very restricted expression in the CNS [21, 22]. The θ subunit may assemble with α , β , γ subunits but remains an enigma [23]. The ρ subunits have been classified as "GABA_C" receptors, but there is now data to suggest that they can in fact coassemble with α and γ subunits [24].

Protein biochemistry and molecular approaches have been used to further define the structure of the pentameric complex. For the most abundant " α – β – γ " arrangement it is now reasonably well agreed that the stoichiometry is $\alpha(2)\beta(2)\gamma(1)$ in the order α – β – α – β – γ [25]. The GABA binding site is constituted by amino acid residues from both the α and β subunits, while as discussed below the benzodiazepine binding site is constituted by amino acids from the α and γ subunits [26, 27]. Given the above subunit arrangement, this explains why there are two GABA binding sites and one benzodiazepine binding site. An important breakthrough in the understanding of the structure of GABA_A came from the elucidation of the X-ray crystallographic structure of the snail acetylcholine binding protein [28]. In essence this protein is an assembly of the extracellular domains of a cysteine loop ligand gated ion channel and as such was ideal for structural studies. The elucidation of the structure of this molecule provided a molecular template upon which other members of the ion channel family, such as the GABA_A receptor, could be mapped, allowing at the very least the generation of models and predictions for experimental investigation.

An exciting concept that is gaining increased attention is that of extrasynaptic receptors [29]. Neurotransmitter receptors are traditionally thought of as being located directly at the synapse, mediating so-called phasic neurotransmission. Evidence is now gathering to suggest that some neurotransmitter receptors are located in the membrane outside the synapse (are *extrasynaptic*) where they respond to “ambient” concentrations of neurotransmitter primarily as a result of diffusion out of the synapse (so-called tonic neurotransmission) [30]. These receptors would influence the overall level of excitability of that neuron and thereby have a potentially profound effect upon its function [31]. GABA_A receptor $\alpha_5\beta_n\gamma_2$ and also GABA_A δ -containing receptors ($\alpha_4\beta_n\delta$ and $\alpha_6\beta_n\delta$) are thought to be predominantly extrasynaptic [32–34]. This will become important when considering the mode of action of gaboxadol (see below). Certainly the functional properties of δ -containing receptors (high affinity for GABA, and therefore activated by the low concentrations of the neurotransmitter that would be found outside the synapse, and a slower desensitization rate) are consistent with such a role.

6.2.2 Pharmacology

The GABA_A receptor has an extremely rich pharmacology. This is summarized in Figure 6.1. The activity of GABA is allosterically modulated by a significant number of different classes of agents acting through what are believed to be independent binding sites. Since the topic of this chapter is hypnotics and sedatives, we will focus our discussion on the benzodiazepine and barbiturates.

6.2.2.1 Benzodiazepine Binding Site. Before the cloning of complementary DNA (cDNA) encoding receptor subunits revealed the diversity of the gene family, GABA_A receptors were defined by their benzodiazepine pharmacology (the so-called

Figure 6.1 Schematic of GABA_A receptor illustrating sites for allosteric modulation. (See color insert.)

BZ1 and BZ2 binding sites). The subsequent investigations into the diversity and structure of GABA_A receptors have enabled a significant insight into their benzodiazepine pharmacology. Only GABA_A receptors containing a γ_2 or γ_3 subunit have a high-affinity benzodiazepine binding site, and since the majority of GABA_A receptors contain a γ_2 subunit, it is likely these are the receptors through which the pharmacological effects of benzodiazepines are mediated [35]. The type of α subunit present in the receptor determines the benzodiazepine pharmacology of that receptor subtype [36], with the β subunit having relatively little influence [37]. As discussed above, the arrangement of the subunits in the receptor complex dictates that the α and γ_2 subunits are neighbors, and indeed the benzodiazepine binding site is constituted by determinants from both the α and γ_2 subunits [27]. Site-directed mutagenesis studies, together with photoaffinity labeling experiments using radiolabeled benzodiazepines, have enabled the identification of a number of amino acid residues in both the α and γ_2 subunits that contribute to the benzodiazepine binding site [38]. While these studies have certainly allowed us to identify the individual amino acids that influence benzodiazepine pharmacology, the resolution and interpretation is still some way from allowing us to use such information to guide rationale drug design. However, a step in this direction comes from the elucidation of the structure of the snail acetylcholine binding protein discussed above; the structure of this protein has been used as a scaffold upon which to lay the amino acid sequences of the GABA_A receptor subunits and thereby visualize the putative structure of the benzodiazepine binding site [27]. A number of the amino acid residues identified by site-directed mutagenesis studies did indeed appear to cluster in the vicinity of each other [39].

6.2.2.2 Barbiturate Binding Site. The site, or indeed the subunit(s), on the GABA_A receptor to which barbiturates bind to exert their activity is currently unknown. This lack of understanding is primarily due to the lack of suitable tools (e.g., high-affinity radiolabeled barbiturates) and the lack of significant selectivity between receptor subtypes, which means site-directed mutagenesis studies which we extensively used to map the benzodiazepine site cannot be so easily applied. What is clear is that barbiturates have two modes of action; at low concentrations they allosterically potentiate the activity of GABA at the receptor, while at high concentrations they can directly activate the receptor in the absence of any GABA [40]. The physiological action of barbiturates is discussed further below.

6.3 SITES OF ACTION IN BRAIN FOR HYPNOTICS/SEDATIVES

It was originally thought that, since GABA receptors are responsible for the primary inhibitory mechanism throughout the CNS, potentiation of this system would result in an overall dampening of activity. Increasing inhibition throughout the entire CNS would logically result in reduced activity and hence sedation. With greater understanding of brain function, this idea is now viewed as rather an oversimplification, and research is very much focused on drug interactions within specific neuronal pathways important for sleep and sedation. To date there have been two major networks identified in the brain that control the sleep–wake cycle. Both originate in the brain stem and project up via different routes to the cortex. The first pathway

Figure 6.2 Key pathways involved in sleep generation and control. Important brain regions are illustrated with excitatory pathways shown in red and inhibitory pathways in blue. The GABA_A receptor subunits found in each brain region are included highlighting presence of different subtypes. Abbreviations; DR, dorsal raphe; LC, locus ceruleus; LDT/PPT, lateral tegmental nuclei/pedunculopontine nucleus; nRT, nucleus reticularis; TMN, tuberomammillary nucleus; VB, ventrobasal nucleus; VLPO, ventrolateral preoptic nucleus. (See color insert.)

projects through the hypothalamus, while the second projects from the pedunculopontine and lateral tegmental nuclei through the thalamus (Fig. 6.2) [41–44].

Three key nuclei are involved in the hypothalamic pathway; the LC in the brain stem sends a noradrenergic projection to the VLPO nucleus. The VLPO nucleus in turn sends inhibitory GABAergic signals to all the major ascending monoaminergic nuclei, including the TMN, dorsal raphe, and a reciprocal connection back to the LC [45, 46]. VLPO neurons show intense firing activity during sleep, and the increased GABAergic transmission inhibits arousal circuits projecting to the cortex [47, 48]. During arousal, excitatory projections onto the VLPO from the LC, dorsal raphe, and TMN inhibit VLPO activity, in turn reinforcing their own firing and promoting wakefulness [49, 50]. This reciprocal arrangement creates a bistable state of either sleep or waking, with rapid transitions from one state to the other [41]. Using c-Fos as an activity label, increased staining is observed in the VLPO nucleus during sleep; in addition the majority of these c-Fos-labeled cells were also GABAergic [51]. In contrast lesioning the VLPO results in animals that have reduced sleep and increased periods of wakefulness [52]. GABA transmission in this pathway is a critical

component [53], and subcutaneous injection of the GABA antagonist gabazine reduces sedation induced by the systemically administered GABA agonist muscimol as well as the anaesthetics propofol and pentobarbital [54]. A recent study focused on the TMN, which receives GABA inhibition from the VLPO nucleus and sends a histaminergic projection to the cortex. Direct injection of muscimol into the TMN produced sedation, and injection of gabazine reduced the sedative effects of propofol and pentobarbital, suggesting that cortical innervation from this nucleus is important in the control of arousal [54]. Interestingly injection of muscimol into the LC did not induce sedation, suggesting that GABA is not so important in this particular projection; however, injection of the sedative α_2 -adrenergic agonist dexmedetomidine inhibits activity in the LC and promotes VLPO activation [55]. Injection of gabazine into the TMN also reduced dexmedetomidine-induced sedation, suggesting that the adrenergic effects feed directly into the GABA-mediated pathway [55]. One recent paper questions the role of the TMN histaminergic innervation showing that using a saponin–hypocretin conjugate to lesion cells in the TMN results in little direct disruption of spontaneous sleep; however, effects on GABA hypnotics were not studied [56].

The second important pathway for control of sleep is the midbrain to thalamus and thalamocortical connection. The PPT–LDT sends a cholinergic projection to the thalamus and, in contrast to the VLPO nucleus, is inactive during non–rapid-eye-movement (REM) sleep but highly active during wake and also during REM sleep [57]. During wake, sensory information is also directed to the thalamus, which then relays this information on to the cortex, and incoming information can be modulated at this level [58]. The activity of the thalamus is controlled by the surrounding nRt, a layer of cells which projects exclusively into the thalamus via a GABAergic mechanism [59]. There is also an intrathalamic network in which GABA plays a major role in controlling the generation of activity through both synaptic and extrasynaptic mechanisms. Control of the flow of information through the thalamus is crucial for sedation, and it is thought that the GABAergic reticular nucleus can act as a gate, reducing the flow of information from external stimuli into the thalamus [59]. Electroencephalographic (EEG) recording reveals some of the properties of brain electrical activity during sleep and wakefulness and shows characteristic patterns of activity in different sleep stages. At sleep onset “spindle waves” (7–14 Hz frequency) appear which last from 1 to 3 s recurring every 3–10 s. These oscillations originate from network activity between the inhibitory neurons in the reticular nucleus of the thalamus and cortical neurons [60]. Slow-wave sleep or delta oscillations occur during deep sleep and follow spindle activity [61, 62]. These are characteristically large-amplitude, low-frequency waves, and it is believed that spindling followed by delta oscillations result in synchronous pulses of calcium within thalamic and cortical dendrites without producing excessive neuronal firing [58]. These conditions are ideal for promoting gene expression and synaptic plasticity [63, 64] and the possible consolidation of memories, which is believed to occur during sleep [65]. These slow synchronous thalamocortical oscillations are abolished during wake and also during REM sleep. These short bursts of activity are characterized by high-frequency, low-amplitude EEG patterns indistinguishable from those during waking. It is likely that these short bursts of REM represent recall of information acquired during waking which is then reorganized and stored by the highly synchronized events during slow-wave sleep [66, 67].

Clearly GABAergic inhibition plays a major role in both these pathways, and drugs which interfere or modulate this activity will have effects on sleep architecture and wakefulness and consequently the process of memory consolidation. The studies by Nelson et al. [54] highlight specific nuclei in the hypothalamic pathway where GABA modulators such as barbiturates and benzodiazepines will produce sedative effects; however, no such studies have been carried out in thalamus. Some recent studies using genetically manipulated mice suggest particular subtypes that are involved in sedation, and these are detailed in Section 6.5. The anatomical distribution of GABA_A receptor subtypes is quite specific and is likely to be related to their individual roles within the CNS. Within the hypothalamic pathway no specific studies have been carried out to investigate which subtypes are involved; however, based on in situ hybridization and autoradiographical studies, it is likely that α_1 and α_2 subtypes play a predominant role, together with β_2 and γ_2 [68]. The thalamus is highly discrete in terms of which GABA receptor subtypes are expressed. In the major part of the thalamus, the ventrobasal VB nucleus, there are two major subtypes: $\alpha_1\beta_2\gamma_2$ and $\alpha_4\beta_{2/3}\delta$ [68, 69]. These subtypes are also expressed differently at the cellular level, since $\alpha_1\beta_2\gamma_2$ is predominantly located at inhibitory synapses, whereas $\alpha_4\beta_{2/3}\delta$ is located extrasynaptically on neuronal cell soma [70]. The reticular nucleus expresses a completely different type of receptor, being predominantly $\alpha_3\beta_3\gamma_2$ [68]. All these subtypes possess different pharmacological and biophysical properties indicating that they subserve different physiological roles and making them amenable to the development of selective drugs [71].

6.4 THE DEVELOPMENT OF SAFER AND MORE SELECTIVE HYPNOTICS

Over the last century the development of sedative drugs has evolved through several phases but has produced some of the most highly prescribed medicines in history. Some of the major drugs and their targets are summarized in Table 6.1. The first synthetic depressant to be used for treating insomnia was chloral hydrate [72]. It was first synthesized in 1832 and is amazingly still in limited use today. It was originally used to treat alcoholics with disturbed sleep and patients with chronic pain who could not sleep. Administering the drug to alcoholics was quite dangerous since chloral hydrate interacts strongly with alcohol: a combination of these two is commonly known as a “Mickey Finn” and produces a powerful “knockout” effect [73]. Like alcohol, chloral hydrate is also addictive and tolerance to the drugs effects occur on extended use. In addition, the drug is carcinogenic [74]. Chloral hydrate is metabolized rapidly to the active component trichloroethanol (TCE), which is known to interact with several ligand-gated channels, including GABA_A, glycine, and NMDA receptors [75, 76].

6.4.1 Barbiturates

The group of drugs that really first popularized the market for treatment of insomnia comprised the barbiturates. Synthesized in 1903 diethyl barbituric acid was the first orally available barbiturate, known as Veronal. This drug was a highly effective sedative, but the effects were very long-lasting and next-day drowsiness was a major

TABLE 6.1 Sedative/Hypnotic Drugs

Class	Trade Name	Dose (mg)	Receptor Target	Status	Issues
Chloral hydrate	Noctec	500–2000 mg	GABA _A / <i>N</i> -methyl-D-aspartate (NMDA) receptors	Low usage	Gastrointestinal upset and diarrhea, tolerance
Barbiturates					
Amobarbital	Amytal	65–200	GABA _A receptors	Relatively low usage for insomnia, some use prior to surgery	Low therapeutic index, tolerance abuse liability
Phenobarbital	Luminal	30–300			
Secobarbital	Seconal	100			
Pentobarbital	Nembutal	100			
Barbiturate-like					
Ethylchlorynol	Placidyl	500–1000	Unknown	Very little use due to low therapeutic index and abuse	Toxicity problems, tolerance and abuse potential, now considered obsolete
Glutethimide	Doriden	250–500			
Methylprylon	Noludar	200–400			
Methaqualone	Quaalude	150–300			
Meprobamate	Equanil, Miltown	1200–1600			
Benzodiazepines					
Diazepam	Valium	5–20	GABA _A receptor potentiation; show some selectivity for the α ₁ -containing subtype of GABA _A receptors	Prescription drug of choice for short-term insomnia, very safe and has high usage but limited for long-term treatment	Abuse potential, tolerance
Alprazolam	Xanax	0.25–0.5			
Clonazepam	Rivotril	0.25–2			
Flunitrazepam	Rohypnol	1–2			
Lorazepam	Ativan	2–4			
Triazolam	Halcion	0.1–0.25			
Other BZ site drugs					
Zolpidem	Ambien	5–10			
Zaleplon	Sonata	5–10			
Zopiclone	Imovane	7.5			

(Continued)

TABLE 6.1 (*Continued*)

Class	Trade Name	Dose (mg)	Receptor Target	Status	Issues
Antihistamines					
Diphenhydramine	Benadryl	25–70	Histamine receptors	Commonly used over-the-counter medicine for mild insomnia	Mild effects, long-lasting drowsiness, dry mouth
Hydroxyzine	Atarax, Vistaril	50			
Triazolopyridines					
Trazodone	Trazorel/Desyrel	50–100	Serotonin 2A and 2C receptor antagonist	Used for treating depression induced insomnia	Hypotension, stomach upset, dry mouth
Nefazodone	Serzone	200–600			
Melatonin	Melatonin	2–10	Melatonin receptor agonist	Sold as a “dietary supplement;” thought to affect circadian clock	Poor clinical evidence of effectiveness

problem. In 1912, phenobarbital was introduced to treat anxiety and insomnia. In addition to its sedative and hypnotic properties, phenobarbital was an effective anticonvulsant and has become one of the most important pharmacological treatments for epilepsy. The highly efficacious nature of barbitals and phenobarbital made these drugs very successful, spawning the synthesis of over 2500 different barbiturates [77]. The effects of these various barbiturates are generally similar, differing primarily in potency, duration of action, and route of administration, some being developed as anesthesia induction agents. The use of barbiturates to treat anxiety and insomnia boomed in the 1950s and grew to a peak in the 1960s despite growing fears regarding addiction liability and a very narrow margin between effective doses and those that produced serious side effects and death [78]. In the United Kingdom alone in 1966 there were over 16 million prescriptions for barbiturates. Growing concern among doctors regarding the abuse and safety of barbiturates together with the availability of the benzodiazepines eventually resulted in reduced use of these drugs [79], and orally administered barbiturates are not currently routinely prescribed for insomnia, although rapid-acting intravenous forms are still utilized to a high degree in anesthesia [80]. Barbiturates act by binding to the GABA_A receptor and enhancing inhibitory neurotransmission in the CNS [81]. As mentioned above, they appear to have a nonselective mechanism with activity at the majority of GABA_A receptor subtypes [82].

6.4.2 Barbiturate-Like Drugs

With the popularity in the use of barbiturates a number of companies developed novel “tranquilizers” which behaved in a similar fashion but were not barbiturate-like molecules. These included ethchlorvynol (Placidyl), glutethimide (Doriden), methylprylon (Noludar), meprobamate (Miltown), and the quinazolones, such as methaqualone (Quaalude) [83]. Unfortunately, despite initial promise, these drugs did not differ from barbiturates in their safety profile, tolerance effects, or propensity to be abused and were not really considered to be an advance in any way. Quaaludes in particular became highly abused in the late 1970s and were one of the most popular recreational drugs of the time [84]. As a consequence they were prescribed with decreasing frequency when safer sedatives became available and are now essentially obsolete.

6.4.3 Benzodiazepines

The popularity of the barbiturates indicated a huge demand for novel anxiolytic and sedative drugs. The highlighted risks with barbiturates and related compounds, especially the low therapeutic window, meant that doctors were becoming more reluctant to prescribe these particular drugs. In 1954 a scientist at drug company Hoffman La Roche synthesized a compound which seemed to be pharmacologically inert. After spending three years on a shelf in the laboratory, the compound was submitted for screening and found to have sedative/hypnotic effects in animals but was much more potent than the barbiturates and safe to administer at high doses [85]. This compound (chlordiazepoxide) was developed and was launched on the market in 1960 as Librium, the first benzodiazepine sedative. The more potent diazepam Valium followed in 1963, and many other related benzodiazepines

followed these. This class of compound was much more potent than previous sedatives and did not have the associated toxicity problems or liabilities on overdose. The benzodiazepines became some of the most successful drugs in history with record prescriptions in the 1970s and 1980s [86]. While the toxicity problems were not an issue, it became apparent that the tolerance and abuse potential seen with barbiturates were still present in the benzodiazepines [87]. Also, while effective treatments for insomnia, benzodiazepines often produced next-day sedation, ataxia, and memory and cognitive impairment [88, 89]. As a result the usage of benzodiazepines for longer term treatment has declined in recent years; however, they are still very effective and fast-acting drugs for short-term use.

As detailed above, in the late 1980s, GABA_A receptors were found to be made up of a variety of subtypes that differed in pharmacology and biophysical properties. It was found that one of the more recent benzodiazepine receptor insomnia agents, zolpidem, demonstrated some selectivity for the α_1 subtype and was relatively more effective as a hypnotic agent than an anxiolytic [90, 91]. Zolpidem has become one of the leading current therapies for insomnia, and similar “nonbenzodiazepine” benzodiazepine ligands such as zaleplon and the soon to be launched indiplon behave in a similar fashion with a small degree of α_1 selectivity [92, 93]. As described below, genetic mouse models have recently identified the α_1 -subtype as having a major role in the sedative properties of benzodiazepines.

6.4.4 Non-GABA_A Receptor Agents

In the last few years, several of the serotonin (5-HT)–modulating antidepressants such as trazodone and nefazodone, which produce sedation as a side effect, have been prescribed for insomnia, especially in depression-related insomnia [94, 95]. These drugs are relatively safe, with no issues regarding tolerance or abuse potential, and probably act via their effects as antagonists at 5-HT receptors.

The hormone melatonin is intrinsic to the control of rhythmic circadian activity in the brain and is released from the pineal gland during the nighttime. Low levels of melatonin have been linked to insomnia and administration of melatonin is believed to be sleep promoting [96]. The mild hypnotic properties of melatonin and its availability as a “natural supplement” have led to widespread use of the agent for insomnia [97]. However, evidence of the efficacy of melatonin is based on limited clinical trial data. Furthermore, melatonin has some properties that would be expected to limit its usefulness as an oral agent, such as short half-life and high first-pass metabolism.

Mild insomnia can also be treated using antihistamines, which produce some degree of sedation. There are many over-the-counter treatments such as Benadryl, Sleep-Eze, and Nytol that contain diphenhydramine or hydroxyzine and will give temporary relief for sleep problems [98]. These agents do tend to cause daytime drowsiness and are not recommended for continuous use since they also exhibit tolerance [99].

6.4.5 Potential New Therapies

There are a number of new therapeutic agents in development for treatment of insomnia and sleep-related disorders. Table 6.2 lists these candidates and gives some

TABLE 6.2 Novel Therapeutics Currently in Development

Class	Trade Name	Receptor Target	Company	Status
Benzodiazepine site				
Eszopiclone	Lunesta	GABA _A receptor potentiation; eszopiclone is a nonselective BZ site agonist similar to diazepam; indiplon, like zolpidem, has some selectivity for the α_1 subtype	Aventis	Launched April 2005
Indiplon	Indiplon		Dov/Neurocrine/Pfizer	Phase III
